4. Pylorectomy or subtotal gastrectomy. In properly selected cases there can be but little doubt that this is the best procedure. It is a fact, in dealing with ulcer of the stomach or duodenum, that the more radical we are, the better our endresults are likely to be. The type of pylorectomy or subtotal gastrectomy to be chosen I believe is a matter of choice with the individual operator. The basic principles are the same in whatever type of operation is undertaken. Undoubtedly, at first, our mortality will be somewhat higher in this type of operation, as against simple gastroenterostomy, but with the proper preparation of patients for operation and the increasing perfection and skill of the operator, the mortality should not be considerably higher than in simple gastroenterostomy. Furthermore, we have the assurance of probable cure and that we are not leaving behind a lesion, which, if not already malignant, may undergo malignant degeneration. Gastric resection undoubtedly should be the operation of choice where applicable, and the only contraindications should be when risk of operation is greatly increased by general or local condition of the patient. Another point, worthy of note, is that if the operation is done under local anesthesia, the postoperative course is extremely smooth, and in the majority of cases the condition of the patient following operation is markedly superior to that following general anesthesia.

Oxalic Acid Production in the Colon as a Factor in Disease Causation

A Preliminary Report

By CLARENCE W. LIEB, A.M., M.D.,
New York.

The biochemical importance of the various sugars reaching the lower bowel is becoming more and more the subject of intensive laboratory and clinical study. Inasmuch as the transformation of histamine from histadine by the colon bacillus is only possible in the presence of an easily available source of carbon such as saccharose or glucose (1) and as histamine is formed only in an acid medium the importance of the sugars in the production of toxins in the intestine is at once apparent.

Neuberg (2) has shown that nearly all reducing substances may play the part of activators in the fermentation of yeast. Von Wassermann and Ficken (3) examined the effect of such activating bodies on the production of toxic substances by intestinal bacteria and could demonstrate a very toxic substance for the mouse in a culture of the Fraenkel bacillus, which is widespread in the intestine, when placed in a two per cent. glucose bouillon. The production of this toxic substance was greatly increased in this instance. The addition of activators increases the toxicity by thirty to forty per cent. The toxic substance has a strikingly critical threshold value. The filtrate is much more toxic than the complete culture. Filtration apparently produces a biophysical solution of the smallest protoplasm particles which are especially effective.

The addition of small quantities of this filtrate to a complete culture acts as an activator similar to the d'Herelle phenomenon. The effect of the activators may be determined by all fermentation excitants and with the colon bacillus. It does not seem to be limited to fermentation quantities but the presence of carbohydrates is always necessary.

The authors assume that similar processes are at the base of intestinal autointoxication. It is not a matter of new bacteriological infection but of activation and formation of toxins. This would explain the normal bacteriological findings and the favorable effect of mechanical emptying of the intestine in contrast to the failure with intestinal disinfection. The toxin with the anaphylatoxin without incubation and which is increased by activation reminds one of the anaphylactic group of diseases in which toxic stimuli are the active cause—vagotonia, exudative diathesis, and arthritism, in which the products of breaking down of administered molecules of albumin play an important part.

Hiss and Zinsser in their latest edition state that "the variety of acids formed by bacteria depends largely upon the nutrient medium. The acids most commonly resulting from bacterial growth are lactic, acetic, oxalic, formic and hippuric acids." Oxalic acid heads this list in toxicity. Judging from the frequency with which the writer found it in human feces by a method elaborated by Connellan, its clinical significance is noteworthy. Where positive oxalic acid reactions have been obtained, the stool has invariably been that of a person with chronically deranged metabolism.

The older writers lay great stress upon the finding of large amounts of oxalate crystals in the urine. Among the symptoms which they mention as the result of oxaluria are headaches, lassitude, mental depression, digestive disturbances, loss of appetite, flatulence and constipation.

Baldwin (4) has been able to develop an experimental oxaluria in animals by feeding large quantities of glucose together with meat. He states that the oxalic acid thus formed is produced by the fermentation of carbohydrates in the stomach. We now know that the latter statement is fallacious and that the oxalic acid thus formed was not formed in the stomach but was the result of bacterial action on the glucose which reached the colon. In like manner can be explained the large quantities of oxalic acid which Naunyn found in the urines of diabetics and obese individuals. In 1879, however, Kobert and Kürsner (5) announced that in animals oxalic acid may produce glycosuria; this has since been confirmed, and Sarganeck has noted the symptom in human poisoning, so that it is probably a constant phenomenon.

TOXIC ACTION.

Oxalic acid and its salts, e. g., salt of sorrel, are quite toxic substances. Oxalic acid is very abundant in the vegetable kingdom in the form of its acid salt, KHC_2O_4 and calcium salt. A number of commonly used articles of diet, such as spinach, rhubarb, figs, cocoa, tea, coffee, plums, tomatoes, strawberries and gooseberries are rich in salts of oxalic acid. Oxalic acid is normally found in the urine, two to six mg. being excreted in the course of the day. An important difference between mineral acids and oxalic acid is the toxicity of the salts of the latter. Not only do free oxalic acid and its acid potassium salt, salt of sorrel, show poisonous properties but even very dilute solutions of neutral sodium oxalate, $Na_2C_2O_2$, act in the same way.

A striking thing about the urine excreted during oxalic acid poisoning is the abundant deposition of crystallized calcium oxalate. The local action upon the kidneys is caused by the clogging of the injured urinary tubules by deposits of calcium oxalate. Attention was first called to oxalic acid as a poison in 1814 by its certainty and rapidity for suicidal purposes. Death has been produced by it in ten minutes. The minimum fatal dose recorded is one dram.

Oxalic acid acts on the economy in two principal ways, according as its solution is concentrated or dilute. When concentrated it causes great pain, followed by violent retching, then sudden dullness, languor, and great debility, death without struggle; when dissolved in twenty times its weight of water, it causes death by acting on the brain, spinal marrow, and heart. It should be noted that the acid, even in weak solution, always exercises a corroding or softening power on the animal tissues. After death from oxalic acid the mucous membrance of the alimentary canal is either soft and pultaceous or entirely destroyed. The stomach usually contains a dark fluid, resembling coffee grounds, consisting chiefly of altered blood. In a few cases no morbid appearances have been discovered.

Autenrieth (6) and Warren have stated that, "On account of the ease with which the organism takes up oxalic acid and its alkali salts, the action of the absorbed poison is rapid. The effects caused by its presence may be attributed to the fact that this acid removes in part from organs, as the heart, and from body fluids (blood) the calcium they require for their life processes, converting it in part into insoluble calcium oxalate. Oxalates diminish the coagulating power as well as the alkalinity of blood. On the other hand they increase the quantity of sugar in the blood. Owing to withdrawal of calcium from the heart, that organ is weakened and finally paralyzed. The quantity of oxalic acid in the liver is noticeably large."

Previously all oxalic acid was made from saccharose or glucose by treatment with nitric acid, one pound of the sugar producing one and a quarter pounds of oxalic acid (7). Hiss and Zinsser (8) state, however, that it can be produced by bacterial action on the sugars.

The foregoing facts may be summarized as follows:

1. Oxalic acid is produced in the colon by the bacterial decomposition of sugars.
2. It is one of the most readily absorbed of the poisons.
3. It produces definite toxic symptoms even in small amounts.
4. It produces calcium deficiency in the circulating blood.
5. It increases the quantity of sugar in the blood.

DIETETIC TREATMENT.

We have been using a dietary containing the minimum amount of cellulose so that as little sugar as possible is mechanically carried into the lower bowel. We believe that the benefits of the smooth diet in colonic diseases are due in large part to a quantitative reduction of activating sugars reaching the lower bowel. A smooth, low cellulose diet mechanically facilitates starch and sugar digestion and likewise lessens peristaltic activity thereby prolonging the absorptive period. We believe that colonic passivity or immobilization produced, in so far as that is possible, by a low or absent residue diet, is just as important in curing colonic pathology as is local rest in other conditions such as an infected lung or a broken leg. Doubtless some of the benefits of a starvation cure are due to intestinal rest and an absence of activating sugars in the colon. Chronic intestinal invalids are notoriously improved for the time by barium meals and enemas. It is very probable that intestinal stasis is a protective mechanism, an effort on Nature's part to produce local rest in the presence of inflammation. I am at the present time experimenting with a residueless diet containing butter, sugars, gelatine, and tryptophan, raw vegetable and fruit juices, in the treatment of extreme colitis and the results to date look very promising.

Recognition must be given to the fact that the sugars as taken in the food do not exist as such on reaching the colon after digestive metamorphosis. This is shown in the following synopsis and is an important guide in devising our dietary menus (9).

Starch.—Constitutes over fifty per cent. of the solid matter of cereal grains and a larger proportion of the total solids of potatoes, bananas, etc. In processes of digestion (especially when cooked) starch is changed to maltose and the latter to glucose.

Glucose (dextrose).—Occurs in large amounts in most fruit and plant juices. Almost all carbohydrates yield glucose when split by digestive ferments. It reaches the large intestine as glucose.

Saccharose (sucrose—cane sugar).—Occurs commonly in the vegetable kingdom. When digested, it is changed into equal parts of glucose and levulose.

Levulose (fructose).—Occurs with glucose in fruits, honey and plant juices. Reaches large intestine as levulose.

Maltose.—Occurs in malted or germinated grains. Large amounts formed by digestion of starch by saliva or pancreatic juice and in turn into glucose.

Lactose (milk sugar).—Occurs in milk. In the intestine lactose is digested into equal parts of glucose and galactose.

COLONIC THERAPY.

This has consisted of daily lavage of one half of one per cent. sodium carbonate (monohydrated) solution until the colon is thoroughly empty. One to two litres of a half of one per cent. calcium lactate solution is then slowly run into the colon and immediately evacuated. The sodium carbonate is used because of its lytic action on all gram negative bacteria, some types of which by their action on certain sugars produce oxalic acid. The calcium combines with the oxalic acid forming calcium oxalate thus preventing its absorption. Some calcium is undoubtedly absorbed through the intestinal mucosa and thereby increases the calcium reserve of the blood.

ORAL THERAPY.

After trying the various calcium preparations we favor the lactate. Four grams can be given daily for a long period of time without upsetting the stomach.

INTRAVENOUS THERAPY.

We have had experience with but two preparations for intravenous use, namely, calcium chloride (ten c.c. of a ten per cent. solution) and afenil (calcium carbimide with urea). We have given ten c.c. of the latter daily for six successive days and find it safe and dependable.

One hundred and sixty-six stools have been examined for oxalic acid. These were from patients all of whom were suffering from some chronic affection. Ninety-six of these were positive for oxalic acid. An analysis of these cases will be left to a later report. A few typical case reports are herein appended.

Case I.—L. M., female, aged twenty-three. A diagnosis of toxic psychosis had been made. The patient had been depressed, uncommunicative and negative for four months. Physical examination was negative except for a proctoscopic examination which showed a markedly hyperemic mucosa and considerable mucus. An examination of the feces showed extra large quantities of mucus and a high oxalic acid content. Blood coagulation time was twelve minutes. After two weeks' intensive treatment complete recovery ensued.

Case II.—F. T., female, aged thirty-eight, was referred with a diagnosis of urticaria, of seven years' standing. All treatment heretofore had been unavailing. Physical examination was negative except for marked *taché cérébrale* and urticarial blotches over the face, abdomen and legs. Feces examination showed highly acid stool, high histamine, and oxalic acid. Within three days after treatment was started the urticaria had disappeared and there was no reappearance after four months. The patient has followed dietary instructions as herein outlined very faithfully and takes a course of calcium lactate every third week.

Case III.—E. L., male, aged thirty-seven; diagnosis, chronic migraine. The patient had had weekly attacks for fifteen years with the exception of a month or two in the summer when he was exercising vigorously. There was chronic constipation of the spastic type. Physical examination was negative except for a blood pressure of 145/90. Feces examination showed a highly acid stool with much mucus and heavy reactions for oxalic acid. The patient has had but one attack since starting treatment four months ago. The blood pressure is 130/85 and the bowels have been perfectly regular. Two months after intensive treatment the stool showed no oxalic acid.

Case V.—B. R., female, aged forty-six; diagnosis, epilepsy of two years' duration, attacks occurring at weekly intervals or even oftener. Physical examination was negative. Feces showed high acid reaction, quantities of intestinal sand (largely calcium) and much free oxalic acid. Patient has had no attacks for six months since being placed on the calcium, dietetic and colonic regimen herein described.

Case VI.—S. G., female, aged twenty-eight; primipara, suffering from pernicious vomiting of pregnancy. Patient had had continuous nausea and vomiting for two months and was exhausted at time treatment was started. Symptoms were completely relieved after the second day's treatment. After one week the calcium medication by mouth, vein and colon was stopped. The symptoms, however, recurred after eighteen hours but subsided directly the calcium regimen was again instituted. After three weeks' intensive treatment the patient was discharged and had had no recurrence to date. She is now in her seventh month of pregnancy.

Diagnosis of Acute Surgical Diseases of Upper Abdomen*

By RALPH F. WARD, M.D., F.A.C.S.,
New York,
Attending Surgeon, Metropolitan Hospital, Department of Public Welfare, City of New York.

Acute surgical diseases of organs of the upper abdomen call our attention principally to the stomach and duodenum, the gallbladder and ducts, and the pancreas. Because of the close anatomical relationship of these organs, and the great severity and suddenness of attack to which they are subject, and also because many or most cases wherein these organs are acutely affected are not seen by the physician or the surgeon at their beginning, it is often difficult, because of a spreading peritonitis, to differentiate exactly which organ has been primarily affected. Here a most careful, painstaking history, which may be difficult to obtain in its entirety from the suffering patient, but which may be enlarged upon by relatives or friends, together with a thorough physical examination, is of the greatest importance, and if time permits, laboratory and x ray examinations should be undertaken.

These acute conditions portray a picture which is tragic, and some surgeons recognizing the need of immediate operation have been in the habit of making the diagnosis upon the operating table. Granted that this sometimes has to be done, because of obscurity of definite localizing symptoms, nevertheless, we should by all available means endeavor to clarify the diagnosis before operation, and by so doing add to our knowledge and diagnostic acumen.

In perforations of gastric or duodenal ulcers, there are two symptoms always present, pain and rigidity. The pain is sudden, violent, agonizing, and prostrating. It may appear after eating or after exertion, and may be difficult for the patient to locate exactly, but usually is in the epigastrium about half way between the ensiform and umbilicus, but may be any place between the two. Later on it may radiate to the back, or as the peritonitis spreads, may reach the right iliac fossa. It is, however, of high origin traveling downward, and is differentiated from the pain in pelvic or appendiceal inflammations or rupture which begin low down and travel upward.

---

*Read before the West Side Clinical Society of New York, April 13, 1922.

The rigidity of the abdominal muscles in perforations of the stomach or duodenum, has many times been described as boardlike, and sometimes is so great that there seems to be no difference between thoracic and upper abdominal resistance to palpation. As nature endeavors to protect the inflamed or ruptured appendix by splinting it with muscular rigidity in the right lower quadrant, so perforations in the upper abdomen are splinted by fixation of the diaphragm and rigidity of the muscles of the upper portion of the abdomen.

According to Muller and Ravdin (1) seventy-four per cent. of perforations will give a history of gastric ulcers which are characteristic, as chronic pain bearing some relation to the ingestion of food, and which in the great proportion of cases is relieved by taking food.

Not long since, I operated upon a patient who had a perforation of the stomach, who gave a history of having had dyspepsia for twenty years, for the relief of which he had taken bicarbonate of soda, two or three hours after each meal for that length of time. Operation was performed six hours after perforation. He made an uneventful recovery. It is the remaining twenty-six per cent. of gastric perforations, where patients never have had any pain or gastric symptoms until the pain of perforation, that tax our diagnostic ability, for they come like a flash of lightning out of a clear sky, striking down a person who was previously in apparently perfect health.

Perforations of the stomach or duodenum give us, aside from the history, the pain of perforation; rigidity of the upper abdomen of boardlike quality; splinting of the diaphragm; vomiting, retching or both; subnormal temperature at first, rising later; increase in pulse and respiration; greatest sensitiveness to palpation in the midepigastrium, and pallor and shock.

A history of previous trouble relative to the gallbladder is usual before an acute attack of cholecystitis, cholelithiasis, empyema, gangrene or perforation. It is noteworthy that a history of pain in the upper right quadrant due to gallbladder disease usually comes on after eating a hearty meal, and is not, as in gastric ulcer history, relieved by taking food. It is relieved by vomiting, belching gas, or by a hypodermic injection of morphine and atropine. In an acute attack, the pain is to the right of the midline in the epigastrium or directly over the gallbladder, radiates through to the back, and under the right shoulder blade, with greatest tenderness to palpation between gallbladder and the midline. There is upper abdominal rigidity most marked on the right side. There is increase in pulse and respiration, and elevation of temperature. If we add to these symptoms a state of icterus, and severe pain on deep palpation a little to the left as well as to the right of the midline, we have a picture of stone or obstruction in the common duct.

Unfortunately x ray examination of gallbladders and ducts for the diagnosis of gallstones have not reached the perfection attained in many other lines, and while some experts claim as high as fifty per cent. finds, I have repeatedly removed choleliths where the x ray has failed to show any shadow. Some of these stones have been the size of an egg. Unless there are some lime salts present with the cholesterin, they do not as a rule show up under the fluoroscope or on the x ray plate. The rapid strides being made in this direction may in the near future give more trustworthy help from the radiographer. At present a negative x ray picture must not deter us from operating in the presence of well marked clinical signs.

It must be remembered also that acute suppurative or gangrenous appendicitis of retrocecal placement may give almost the same picture as that of gallbladder disease, but there will not be splinting of the diaphragm. Again, both gallbladder and appendix may be affected at the same time.

To quote from W. J. Mayo (2): "There is a curious relationship between acute perforations of the gallbladder into the free peritoneal cavity and acute perforative appendicitis. I have seen a number of simultaneous perforations of the gallbladder and appendix. In these cases the gallbladder has usually contained stones, the pus has had a strong colon odor and its bacterial flora has been similar to that in the pus escaping from the appendix. The first case of this kind under my observation resulted most unfortunately, as the condition of the appendix escaped attention. The gallbladder had perforated and a beginning septic peritonitis with a good deal of turbid fluid was present. The patient had been ill with acute symptoms for more than seventy-two hours. I therefore removed the stones as quickly as possible, drained the gallbladder, and evacuated the fluid contents of the abdomen, made a rapid toilet, and inserted drains. The patient died forty-eight hours later, when I found that there had been a perforation of the appendix, with an abscess imperfectly walled off, into which a fecal concretion had escaped. Had I discovered the true condition of the appendix at the time of operation there is little doubt that the patient would have recovered. Since that time, I have always examined the appendix in cases of acute perforations of the gallbladder, and in a number of instances have seen similar conditions. It would appear that, in such cases, the infection started in the appendix and was carried through the portal circulation to the gallbladder already infected and containing stones."

An experience of my own antedates the publication of the quotation from Dr. Mayo (2). In 1912, while operating in a case of acute suppurative cholecystitis, I found the appendix also involved in an acute, virulent inflammation with beginning gangrene. Since then I have removed the appendix in every gallbladder operation undertaken, whether it seemed to be pathological or not. It must be conceded that we can not ignore the appendix, and its influence upon acute surgical diseases of the upper abdomen.

In acute suppurative or gangrenous pancreatitis, we have the most severe, fulminating type of surgical disease that occurs in the abdominal cavity. Because of the close anatomical relationship of the gallbladder and ducts to those of the pancreas, through the diverticulum of Vater, and the ducts of Wirsung and Santorini, the head of the pancreas may become infected, where there is damming up, due to stones, infection or pressure at the papilla of Vater. Not only through the ducts, but as Deaver in his paper on pancreatic lymphangitis says—"The gallbladder, bile ducts, pyloric region of the intestines and the second part of the duodenum, through their efferent lymph channels, are placed in intimate relation to the head of the pancreas, and it is the head of the pancreas that is most frequently involved in pancreatitis associated with other upper abdominal disease. The course of infection has time and again been observed at the operating table in gallbladder disease."

C. H. Mayo (4) says: "The lymph drainage from the head of the pancreas passes through the lymph glands of the common and hepatic ducts. A cholecystitis causing great enlargement of these glands can produce pressure and jaundice or a lymph borne infection of the pancreas."

Thus it can be seen how the head of the pancreas may be easily vulnerable to attack by infection because of its relationship, through lymphatic channels, as well as through its duct system. It also shows that a history of previous gallbladder trouble may be expected in many cases of acute pancreatitis.

The pain in acute pancreatitis is sudden, intense, and agonizing. It is in the midline, nearer the ensiform than the umbilicus. There is at first vomiting and retching. The patient is in shock and collapse, with a rapid, weak, pulse. He will be bathed in a profuse perspiration, and his face will be of a deathly pallor, or will be cyanotic. The temperature at first is subnormal, but rapidly rises. There is upper abdominal rigidity, often accompanied by retraction at or below the level of the umbilicus. The symptoms are more severe, and the shock more intense than in stomach perforation or that of the gallbladder. Fortunately these cases are not common. When one has seen a patient in this condition it will produce a mental picture never to be forgotten.

The treatment of these acute diseases is strictly surgical, and that without delay. Every hour without operation jeopardizes the life of the patient, while if operated upon within the first few hours, his chances are good. You might consider that the patient is too weak to stand the anesthetic, but on the contrary it lessens the shock, relaxes the diaphragm, and under its influence the pulse and respiration are markedly improved.

Without going into the surgical technic, may I say that the Mayo incision, or one I have used, from the ensiform curved to the outer edge of the right rectus and then straight down, gives the required room for thorough exploration of the stomach and duodenum, the gallbladder and ducts, the pancreas, and the appendix, all of which must be investigated, because of their intimate interrelationship in acute diseases of the upper abdomen.

Upper Abdominal Disease in Relation to Insurance Risks*

By MOSES BEHREND, M.D.,
Philadelphia.

The paramount question for medical examiners to decide is whether the prospect for insurance is a better risk before or after operation. This depends in a measure from what viewpoint you are considering your applicant. If you are an internist your opinion may differ widely from that of the surgeon. I believe that the surgeon is in a better position to decide whether the man who presents himself for insurance is a good risk or not. The surgeon sees the lesion, the medical man perhaps guesses at its existence. If the physician is a good medical surgeon, that is, one who recognizes the importance of calling a surgeon, a better opinion is forthcoming from this type of physician. Again, a physician whose opinion can be depended upon is the one who is always present when the operation is performed on his patient. In a given case there may be as many opinions as there are physicians in this room but the most important question is to give an opinion based on facts and experience. Such experience can only be acquired by long practice.

As we shall devote our attention mainly to the upper abdominal conditions a question of importance is the frequency of the occurrence of cancer grafted on a lesion, be that a gastric or a duodenal ulcer, gallstones, pancreatitis or some other chronic irritant which predisposes to malignancy. The estimates of different observers vary greatly, some putting the cancer incidence at five per cent. while others place it at over sixty per cent. in cases of ulcer of the stomach. I have never seen a case of carcinoma of the duodenum following a duodenal ulcer. This is an exceedingly rare complication. There is no question in my mind that gastric ulcers predispose to cancer of the stomach. While it is often difficult at operation to decide whether a lesion is definitely a cancer or not there are undoubtedly a great many malignant cases in this group. The busy surgeon encounters many cases which could be used to illustrate this point but the history of the following case will suffice.

---

*Read before the Philadelphia Medical Examiners Association, November 6, 1922.

CASE I.—The patient, who was referred by Dr. V. A. Loeb, had suffered for many years from indigestion. He lost weight, had almost continual pain and no appetite. At operation an ulcer was found on the posterior wall of the stomach which resembled a cancerous condition. After a rather difficult operation the diseased structures were excised and the edges of the stomach were reunited. The patient made a good recovery. Much to our surprise the histological report showed benign ulcer of the stomach.

As medical examiners you are not so much interested in the applicant who has cancer at the time of the examination because these cases are readily diagnosed and rejected. This is true in a large majority of the patients examined. Occasionally the human error will creep in. Infallibility in diagnosis does not exist.

GASTRIC OR DUODENAL ULCER.

The most interesting and the most important point for you to decide is whether these applicants with benign conditions are better risks after operation than before. My feeling is that if you as examiners possess absolute knowledge of the existence of a gastric or duodenal ulcer, especially a gastric ulcer, the applicant ought to be rejected or given an advanced rating. The reason is that the complications of perforation or hemorrhage are serious and may arise at any time to cause death. We have as an example a case of a man eighteen years old who was admitted to the Jewish Hospital with the history of having had hematemesis on several occasions. On account of this history the operation was scheduled for the following morning. During the night, however, he had a concealed hemorrhage which was not recognized by the nurse. Before any remedial measures could be applied the patient died.

HEMORRHAGE AND PERFORATION.

Hemorrhage and perforation occur in about five per cent. of cases. Everyone recognizes the seriousness of perforation of an ulcer. Those who have witnessed operations for gastric or duodenal ulcers will note the fact that it is impossible to cure a hard nonresistant ulcer by medical means. These are the types that degenerate into malignant tumors. At Boston in conversation with one of the prominent surgeons of Chicago we asked his opinion of the result of Sippy treatment. His answer was that four out of every five patients come to operation. Two thirds of this particular surgeon's work consists of gastric surgery. I would therefore consider a patient undergoing the Sippy treatment as only a fair risk while a patient who has been operated upon is a first class risk. The conditions under which this opinion is given is that it must have been performed by a surgeon of reputation and that the ulcer must have been removed by excision.

The question might be asked is there not danger of a gastrojejunal ulcer following operation where a gastroenterostomy has been performed. Yes, but the incidence of this complication is less than one per cent. and is therefore a negligible factor. It must be borne in mind that all the complications of a primary ulcer may be found in a marginal ulcer. Secondary operations are as successful as the primary; the results are gratifying, while the health of these individuals is usually better than after the primary operation. Notwithstanding the possibility of a second recurrence the patient is often a better risk after this operation than after the first. Several examples to illustrate this point could be given but it will suffice to refer to two cases admitted to the Mt. Sinai Hospital. These cases had primary operations, both had gastroenterostomies performed and then marginal ulcers developed, the one having continuous pain, the other hemorrhages which almost cost her life. In the first case the gastroenterostomy was excised, the openings in the stomach and duodenum were enclosed, the food was allowed to pass from the stomach by means of the pylorus. The second case was a desperate one on account of frequent hematemesis. The patient's hemoglobin was between twenty-five and thirty per cent. She was pale, apathetic and emaciated and not always cognizant of her surroundings. A few hours before operation she was transfused with whole blood. The ulcer was excised and the gastroenterostomy was renewed. Both these patients made a fine recovery, the former being able to eat foods which she was unable to enjoy before; the latter regained her health wonderfully, the hemoglobin before she left the hospital was seventy per cent. These two cases are better risks now than they were before the second operation.

GALLBLADDER DISEASE.

Another upper abdominal condition that must be reckoned with is gallbladder disease. While gallbladder disease is not nearly so serious a condition as ulcers of the stomach and duodenum in relation to insurance risks still the cancer incidence following cholelithiasis especially must be borne in mind. Cancer of the gallbladder follows in about five per cent. of cases. The percentage seems greater at times considering the large number of malignant cases that one encounters in series. It is a well known fact that about twenty per cent. of the cases autopsied have latent gallstones. Perforation of the gallbladder is a rare affection, occurring in less than one per cent. of cases. The symptoms of this accident are similar to those of ruptured gastric or duodenal ulcer.

Probably gallbladder disease does not interest the medical insurance examiner as much as gastric and duodenal ulcer on account of the comparative infrequency of gallbladder disease in men as compared to women, provided the same conditions pertain now as formerly when women were not solicited to carry insurance on account of them being poorer risks than men.

When one considers gallbladder disease in relation to insurance risks there are three classes that present themselves. 1. Those with frank gallstone attacks. 2. Those who have gastric symptoms related to gallbladder disease. 3. The latent cases of cholelithiasis. In those who have had gallstone colic there is no question that they are better risks after operation than before on account of the danger of the complications and sequelæ such as cancer, rupture of the gallbladder, stone in the common duct and acute pancreatitis. In the second class of applicants for insurance we are compelled to make a differential diagnosis between some gastric or duodenal lesion and gallbladder disease. This is at times difficult without resorting to all the laboratory aids. Granted that it is not your province as medical examiners to apply these helps in diagnosis it would be safer from your viewpoint to rate these individuals as fair risks only. In the third class of prospects there is no means to determine the existence of gallstones so long as they are not symptomatic. It makes little material difference because at autopsy latent gallstones are never a cause of death.

JAUNDICE.

As a matter of argument it would not be advisable to accept persons who are jaundiced. Jaundice is not always present in gallbladder disease, occurring in fifteen per cent. of cases. When jaundice is only a temporary condition following an attack of acute cholelithiasis not much importance need be attached to it from the medical aspect, but if it persists, as in cases where the common duct is obstructed by a stone, chronic pancreatitis or malignancy in the pancreas or some portion of the gallbladder passageways we have a real problem. In those having a temporary cholangitis medical treatment may suffice unless gallstones are present when a cholecystectomy by the open method should be performed. At the time of operation the common duct must always be examined to eliminate a stone. In benign cases in which a cholecystectomy has been performed the prospect may be classed as a good risk.

STONE IN THE KIDNEY.

The destructive effects at times of stone in the kidney renders this condition an insurance risk of no small importance. History records many kidneys that have been rendered functionless by a stone too large to descend the ureter. The functionless kidney is not always recognized immediately until the continuous obstruction to the flow of urine has caused considerable damming back of urine, a consequent abscess and the entire destruction of the kidney parenchyma. This may take a long time to accomplish but eventually the results of the colic will be felt. Many patients pass small stones without any effect on kidney secretion. There are also many cases of latent stones that do not give any trouble at all but which are found accidentally on x ray examination. Stones in the kidney predispose to cancer of this organ by acting as a persistent trauma. In two months we operated on three patients with cancer of the kidney superinduced by renal lithiasis. When stones exist in both kidneys or colic has attacked both kidneys we are facing a real problem. When both kidneys harbor stones the largest and the most obstructive should be removed first. As insurance risks these cases should be rated high. Even if the stones have been removed enough damage may have been inflicted to render the patients poor risks.

It is remarkable how healthy patients are who have had one kidney removed. My records show many patients in perfect health as a result of a nephrectomy. They are well because the kidney removed was not functionating at all, the work having been performed by the healthy kidney. My feeling is that if these persons desire insurance they should be given an advanced rating.

It is evident that the subjects of tuberculosis of the kidney are not insurable. Here, too, one is surprised how well these patients remain after the diseased kidney has been removed.

Hematuria of the kidney nontuberculous and not due to stone is usually caused by a hypernephroma, which means a sarcoma in the majority of the cases. This is a curable affection if reached early and a nephrectomy performed.

GASTROPTOSIS.

Gastroptosis may simulate any of the benign intraabdominal conditions. This occurs mainly in women. When associated with splanchnoptosis it is a purely medical condition. Movable kidney may also be included in this class. While these various phenomena usually occur as a result of the stretching of the normal peritoneal ligaments due to an absorption of fat, surgery has only a limited field here. When the stomach alone is ptosed a reduplication of the gastrohepatic omentum may relieve the symptoms. In cases of movable kidney we may occasionally do some good by sewing the kidney in position. The object of bringing in this class of cases for argument is for the purpose of reminding you that while the condition is symptomatic it is perfectly benign. These prospects should be considered good risks.

Occasionally the appendix may be considered an upper abdominal organ. This is found when the colon fails to rotate as it should. I have found the appendix in the epigastric region on several occasions. The situation of the appendix in the region of the gallbladder is more common than in any other part of the abdomen except the right iliac fossa. An applicant who has had chronic appendicitis, provided he never had an acute attack, should be considered a good risk. If there is a history of an attack of acute appendicitis, no operation having been performed, then I believe the risk ought only be classed as fair. If the person submitted to an operation then he should be rated a good risk. The rule in cases of appendicitis seems to hold here also that after operation the patient is a better risk than before operation.

It is well understood by all that any case of cirrhosis of the liver, Banti's disease, and the various anemias associated with disease of the spleen can never be considered insurable risks.

In conclusion I must admit that I have entered on this subject with much trepidation on account of my inexperience with subjects of this character. I have never been a medical examiner; the thoughts expressed here are entirely opinions that I have on the subject were I to be called in a given case. The opinions expressed may differ widely from yours or from the instructions that you receive relative to this work which carries with it such great responsibility. You want to be just to all; at the same time it is essential for you to be well informed physicians so that as few mistakes as possible will be made.

Finally we have touched the mere outline of the diseases that may affect the abdomen in a medicosurgical sense. It is my belief that the prospect is a better risk after operation than before.

1738 Pine Street.

Carcinoma, with Especial Reference to the Alimentary Tract*

By WILLIAM EARL CLARK, M.D.,
and
MATTHEW WHITE PERRY, M.D.,
Washington.

Any discussion by a clinician on the subject given would be incomplete without a tribute to the many men who are devoting their lives to experimental research in the problem of cancer. Probably no one subject in medical research has presented a more complex and difficult problem to its workers. We, in practical medicine, are likely to overlook the debt we owe the research laboratory worker, and do not often enough realize that largely to him is due credit for the greater part of that scientific knowledge on which successful practice is based. The great hope of the future in the problem of cancer centres around the experimental laboratory. No problem in medicine is more closely dependent on animal experimentation and the hope of the future lies in the maintenance of this type of study and research.

Fortunately there is abundant material on which to work in an experimental way. Cancer is very common in the lower animals. Melanotic sarcoma in dapple gray horses, and mammary carcinoma in dogs are not infrequent. Many fowls are subject to sarcoma and fish to carcinoma. Most frequent of all, however, is the occurrence of carcinoma in rats and mice, and fortunately so, for these animals furnish excellent material for research work and in them it is easy to transmit growth by inoculation of bits of malignant tissue.

Much has been learned concerning the biology of tumors from the study of transplanted rat and mouse cancer. The occurrence of spontaneous cancer, while relatively frequent, has not been frequent enough to supply the large numbers necessary in experimentation. Since the discovery that cancer could be transplanted, investigation of such transplant tumors has engaged students. Transplant tumors have been shown to be in many respects fundamentally different from spontaneous tumors. It has been said that transplant tumors, "Merely represent artificially produced metastases of one animal into the tissues of another and are always growths of cells derived from the cells of the original tumor animal and not the cells of the host. The spontaneous tumor, of course, represents growth of the tissues of the animal that bears it. The inoculated animal, in all probability, would never have had a tumor of its own tissues. Thence the conditions must be quite different from what they are in the animal that suffers maligant transformation of its own tissues. As evidence that there is such an essential difference, a large proportion of implanted tumors may undergo spontaneous disappearance and cure, which apparently never happens with spontaneous malignant tumors." (1)

The great advantage which could result from study of spontaneous tumors is as evident as is the limitation attached to the study of transplanted tumors. The problem is the obtaining of sufficient animals with spontaneous tumors to supply the demands of research work. Of late it has been shown that spontaneous tumors may be artificially provoked, and production in this way of spontaneous tumors in experimental animals promises a solution to the problem. By imitating in animals conditions which are known to provoke cancer in man, and by taking advantage of conditions that have produced cancer in animals, it has been possible to induce spontaneous cancer. We have long known that epitheliomata frequently arise in workers in tar. Applying this knowledge, Japanese workers, who seem at present to be doing some of the best work on the problem, have produced such tumors on the ears of rabbits and the backs of mice by repeated paintings with tar (2). In the second of these ways, that is by imitating conditions which are known to have produced cancer in animals, it has been possible to produce rat gastric carcinoma in a number of instances. Febiger (3) accidentally found that certain types of rates which lived largely on cockroaches commonly had chronic gastritis and often cancer of the stomach. Investigating this further he found that the cockroaches were infested with a parasitic worm which when ingested by the rat bored into the gastric mucosa of the animal. The resulting irritation apparently served as a sufficient etiological factor to produce carcinoma. Experimentally by feeding such infested roaches he has been able to produce spontaneous gastric cancer in a number of cases. Thus is opened up hitherto unobtainable material for research, material not limited biologically as is transplant tumor material and definite hope for further progress may be held.

It is also possible by so crossing animals in which tumors have spontaneously appeared, in other words by selective breeding, to produce strains of rats in which spontaneous occurrence is relatively high (4).

Among the many practical problems which have been studied in transplant tumors is that of the effect of diet on the rate of tumor growth. We have all no doubt wondered, in handling cases, whether by restriction of diet along certain lines we might slow up growth or lessen metastases and thus lengthen life. It has been shown that a diet which provides the most satisfactory growth of somatic cells is also most favorable to tumor growth. In transplanted cancer, however, the administration of cholesterol parenterally or orally has the power of tremendously stimulating tumor growth and metastasis. Accordingly diets rich in this substance would seem to be bad, and have been so shown in transplant tumors. Whether or not this holds true for spontaneous tumors is not known. Some evidence is to the contrary. Work along this line has been done by Robertson and Burnett (5) and confirmed by Sweet and his coworkers (6). The latter were able to obtain from a tumor which had never previously yielded metastases, by the administration of cholesterol by mouth, 104 metastases out of 116 inoculations. It has also been found that diets deficient in certain aminoacids, essential to cellular growths, inhibit tumor growth also, as would be expected. Such diets, however, would obviously be detrimental to the general health of the host.

---

*Read before the Medical Society of the District of Columbia, November, 1922.

All in all, in an experimental way, a tremendous amount of truth and knowledge is being uncovered in the experimental laboratory, and this constant accumulation of bits of knowledge will eventually supply the key to the cancer problem.

The etiology of cancer is such a broad subject that we shall attempt only a brief statement of a few practical aspects; the rôle of chronic irritation, and the rôle of heredity. Both have occupied a prominent place in recent thought. Formerly not seriously taken, of late the feeling has become more and more pronounced that both play large and important rôles. Especially is this true of chronic irritation. It is repeatedly and in many ways shown that chronic foci of irritation or inflammation represent potential precancerous lesions. One has only to recall the frequency of cervical carcinoma in the lacerated cervix of the multipara as compared with its infrequency in that of the nullipara; the frequency in which it used to occur in the chimney sweep; in the Irishman repeatedly burning his lip with his short clay pipe; in the workers in paraffin and wax and tar; in those with chronic varicose leg ulcers; and in many other instances, to be impressed with this factor. Less familiar instances of the same may be of interest. In Kashmir the natives are in the habit of carrying a charcoal burner suspended beneath their robes against the anterior abdominal wall. Epithelioma of the abdominal wall is more frequent in this locality than in any locality of the world.

The publications of the British Imperial Research Cancer Fund cite other interesting examples of this fact. In certain parts of India cattle are made to draw loads by means of a cord passed through a hole at the base of the horn. In such cattle malignancy of the pulp of the horn is relatively frequent. In Egypt malignancy of the bladder is common and it is thought due to the prevalence of bilharzia, acting as a chronic irritation to the bladder wall. Many other examples are cited in this report such as the great frequency of malignancy of the mouth in betel nut chewers, its absence in the glans penis of circumcised races. Bloodgood has studied a large series of malignant conditions about the oral cavity and is of the opinion that recognizable precancerous lesion, in the form of a chronic area of irritation or inflammation, existed in practically all. It is this indisputable evidence which makes one search for the factor of long standing irritation as a precursor of gastrointestinal cancer. That such exists in the greater frequency of gallbladder cancer where gallstones are present, and in the greater frequency of cancer of the colon in the presence of the chronic inflammation of diverticulitis, is generally accepted. That chronic gastric ulcer is the precurser of most gastric carcinoma is also held in many quarters. It would seem logical from what has been said that it should be. There is much difference of opinion, however, in regard to this. The Rochester and Chicago clinics, from analyses of large series of cases, strongly hold the opinion that in the largest group of cases of gastric carcinoma they obtain a typical history of chronic peptic ulcer, in most instances dating back for years. They have carefully studied specimens removed in the operating room and have found in the edge of large callous ulcers beginning cancer. In other words the patient gave symptoms typical of ulcer and what seemed to be an ordinary callous ulcer was removed at operation and after careful study showed that cancer had started in the edge of the ulcer.

Most of us in clinical medicine in the East have had an impression differing from this view. It seems the largest group of cases that we see with cancer of the stomach state that they have rarely had indigestion until the onset of the present complaint. That there are other fundamental causes than chronic irritation is shown by the fact that duodenal carcinoma is practically never seen, while duodenal ulcer is much more frequent than gastric ulcer. It is said that the difference in reaction of the contents of the two areas may explain this phenomenon, that gastrointestinal carcinoma is practically confined to that part of the bowel where an acid reaction exists. While this largely holds true for the stomach and large bowel, it does not for the mouth and esophagus where alkaline reactions exist. Probably the more likely cause lies in the fact that more highly specialized structures are more prone to malignant change and that the stomach and colon represent more highly specialized structures than does the small bowel, the latter more nearly approaching the character of primitive gut.

We have reviewed our cases of gastric carcinoma to find the percentage in which we obtained a history suggesting preexisting ulcer. Of fourteen consecutive cases, carefully worked up, nine gave no history suggestive of a preexisting ulcer (sixty-four per cent.) Two gave a history typical of preexisting ulcer (fourteen per cent.) Three gave a history of indigestion which could possibly have been due to a gastric ulcer (twenty-one per cent.)

Of peptic ulcer in general we have found the percentage of gastric ulcer lower, and that of duodenal ulcer higher than ordinarily stated. Of seventy-one consecutive cases of peptic ulcer diagnosed during the past twelve months, seventy-nine per cent. have been duodenal ulcer and twenty-one per cent. gastric ulcer. In our opinion the incidence of gastric ulcer is less frequent than ordinarily stated.

The question of heredity in cancer is one frequently asked us by our patients, and is a vital one. Should the offspring of cancerous stock be more closely watched for early malignancy? There seems to be more of a tendency for clinicians to feel that there is an element of heredity in the condition and certainly there is experimental evidence of such. Slye (4) in the article already quoted has shown that by selective breeding not only may spontaneous cancer become more frequent but there is also an hereditary tendency for involvement of the same organ to occur, as for example cancer of the uterus in successive generations. A few years ago, however, Hoffmann for the Prudential Life Insurance Company, investigated the problem from the viewpoint of their statistics, concluded that while cancer was on the increase, there was no proof of heredity. A. S. Warthin (7) on the other hand, from the pathological material at the hospital of the University of Michigan, handled by him from 1895 to 1913 and compared with accurately taken histories, draws opposite conclusions, and his statistics are convincing. So striking are his conclusions that we have copied them as a whole: a, A marked susceptibility to carcinoma exists in the case of certain family generations and groups. b, This susceptibility is frequently associated with marked susceptibility to tuberculosis and also reduced fertility. c, The multiple occurrence of carcinoma in a family generation practically always means its occurrence in a preceding generation. d, The family tendency is usually more marked when carcinoma occurs in both maternal and paternal lines. e, Family susceptibility to carcinoma is shown particularly in the case of carcinoma of the mouth, lip, breast, stomach, intestine and uterus. f, In a family showing the occurrence of carcinoma in several generations there is a decided tendency for the malignancy to develop at an earlier age in the members of the youngest generations. In this case it often shows an increased malignancy.

In our work, in twenty-five consecutive cases of gastrointestinal malignancy there was a family history of malignancy in only one (four per cent.). Patients were questioned as far back as grandparents, uncles and aunts. As a control twenty-five consecutive cases of nephritis were reviewed. A family history of malignancy was obtained in only one case.

The problem of heredity is far from settled. Most of the data on which our opinions are based are obtained from large hospital records where the class of patients handled makes it difficult to obtain accurate and reliable histories. The factor of error in such is obviously great. We who are handling an intelligent and reliable class of patients are in a much better position to obtain accurate information on such subjects. It is from the private clinic that the most reliable statistics should come.

Approximately thirty per cent. of all cancers are cancers of the stomach. Two thirds of all gastrointestinal cancer are of the stomach. Cancer of the sigmoid and rectum is relatively frequent but nothing like so frequent as of the stomach. It is almost universally believed that cancer is on the increase but, as has frequently been pointed out, we must bear in mind the remarkable extension of life as a result of vaccination and hygiene. Within thirty years there has been an extension of ten years of life expectation. Many more people are reaching a cancer age than formerly. The increase in external cancer is not out of proportion to this extension of life. Internal cancer has apparently increased out of proportion but one must remember that the correct diagnosis of internal cancer is a comparatively recent achievement in diagnosis. Thus, on analysis it is evident that there is probably no real increase in the incidence of cancer other than that due to more people living to the age when malignant changes are prone to occur.

Since this paper was written an article has appeared confirming this opinion (10). W. T. Howard, in an analysis of the vital statistics of Baltimore, finds no evidence of increase of cancer. The records of an individual community such as this, where skill in diagnosis may be assumed to have been above the average, are probably the most reliable we have.

Our only hope in early recognition of gastrointestinal cancer is to endeavor to get the patients suffering with indigestion to submit to a careful diagnostic study. This is especially important if the patient is at or near the cancer age.

There are no definite pathognomonic signs of cancer that can be recognized in the early stages of cancer of the alimentary tract. The symptoms are often like the indigestion that one encounters in less serious disorders. Any patient, however, with a persistent indigestion, should be suspected of malignancy until it can be proved otherwise. One should not wait for the appearance of marked anemia and loss of weight.

In cancer of the esophagus difficulty of swallowing is usually the first symptom. It will occur irregularly after coarse articles of food. Gradually this symptom will become more persistent and after a time the patient will be able to swallow only soft or liquid foods. Pressure or discomfort in the region of the cardia or in the lower chest will be added, also eructations, and after a period weight loss, anemia and other constitutional signs. The passing of a stomach tube will often locate a dilatation above the growth containing excess of mucus and food which has stagnated there. The x ray is the greatest aid in early diagnosis. Cardiac spasm gives a typical picture with the x ray, very different from the narrow irregular bismuth tract seen in malignancy.

Patients with cancer of the stomach can be placed in two groups according to the histories given. First, there is a small group giving a typical history, x ray appearance, and even in the operating room the appearance of a callous peptic ulcer. In the edge of the ulcer one can demonstrate beginning cancer. As a rule after an ulcer has undergone malignant change the pain may be less severe but is more persistent and exhausting. The patient soon develops a fear of eating. Loss of weight begins. He complains of belching, often sour eructations, bloating, nausea and vomiting. There is less food ease, less soda ease and the chief means of relief is from vomiting or from opiates. The next group, and the larger group in our experience, is one in which the patient has previously enjoyed excellent digestion until the onset of the present symptoms. The early signs are much like simpler forms of indigestion, loss of appetite, epigastric discomfort, pressure, ache, bloating, nausea and vomiting. Some give histories of indigestion suggestive of chronic cholecystitis, or appendicitis, or simply vague nervous indigestion. Others present themselves for examination on account of hemorrhage, or perhaps the appearance of a lump in the epigastrium.

Certain familiar points in examination seem worth emphasizing. In a case of suspected malignancy the patient shrould have the bowel well cleared with a dose of castor oil or an enema. Another important procedure is to wash out the stomach with a soft rubber tube. In this way one gets rid of, not only the distended stomach, but distended loops of gut that would make the examination difficult and prevent one palpating a tumor mass. The stomach tube will also reveal undigested food, mucus and changed blood which have stagnated in the stomach. The odor of gastric contents in these cases is usually pungent, rancid and disagreeable. Test meal extracts may show high acid values in group 1 (The cases appearing to be simple calloused ulcers). In the other group one will find diminished free hydrochloric acid and peptic values. In the average case, both free hydrochloric acid and total acidity are low and lactic acid is found in many cases. The finding of Oppler Boas bacilli is frequent in the cases with obstruction and not infrequently in those without obstruction. The blood examination in the early cases may show very little departure from normal, unless there have been recent hemorrhages. As the disease progresses an anemia develops that is a typical secondary or chloranemia. Later the leucocytes usually increase moderately. The study of the feces is most important. In practically all cases there are soft spots which tend to ooze blood or ulcerate and occult blood can be demonstrated in the feces in a large proportion of cases. X ray technic has been so improved that small early defects can be recognized. Information gained in this way will reveal practically all cases. There are no specific tests. Attempts at serodiagnosis have failed. A most interesting laboratory test, holding forth the hope of possible help in early diagnosis, and especially in differential diagnosis, is the variation in the blood sugar curve recently emphasized by Friedenwald and his associates (8). It has long been known that the blood sugar was high in carcinoma in general. These workers have elaborated earlier work along this line and have shown that after administration of one hundred grams of glucose on a fasting stomach there occurs a rather characteristic curve of sugar tolerance. This occurs in all carcinomata, it is asserted, but differs sufficiently in gastrointestinal cases to make it of diagnostic importance. They are of the opinion that it is of great aid even in early cases, but that it grows progressively more so as the case advances. Our own experience with this test, in a small series of cases, has been disappointing.

Cancer of the large bowel occurs most frequently in the cecum, sigmoid and rectum. Cancer of the large bowel is usually relatively slow in growth and there seems to be less tendency to metastasis. Symptoms common to the group are increasing constipation, pains of a peristaltic character, and finally symptoms of obstruction which may set in suddenly. The patient also usually gives a history of passing an excess of blood, mucus, and often pus. The more general use of the proctoscope can not be too much insisted upon. Every case of hemorrhoids should be so investigated.

We have obtained the best surgical results in cases of cancer of the large bowel. Most of the growths have been removed after a twostage operation. A preliminary colostomy is advised and after the obstruction has been relieved and the distended proximal gut has gone down to a normal size and the patient gotten in better condition, the growth excised.

In conclusion we would emphasize that patients who are at or near the cancer age should not be allowed to go for months with an indigestion that is of a progressive type, with more or less continuous symptoms, especially with weight loss and increasing anemia. Such patients should be put through a careful diagnostic study including gastrointestinal x ray examination. If the result of this study is strongly suggestive of malignancy, these patients should be submitted to exploratory operation. If we wait for months, until the more definite symptoms occur, the growth will usually be advanced to such a stage that no successful cure can be obtained. In this way our percentage of cure may be considerably improved.

The author's references will appear in his reprints.

Carcinoma of the Esophagus

By JOSEPH M. MARCUS, M.D.,
and EDWARD A. ARONSON, M.D.,*
New York.

There are many of us who occasionally meet with a patient in whom we have completely satisfied ourselves as to the presence of a tumor and, on its disappearance independent of any treatment, we are compelled to admit how little our knowledge of medicine is after all.

Unquestionably, benign and malignant growths disappear, as noted from the large number of cases reported in the literature. According to Ribbert, spontaneous cure of malignancy depends on the biology of the cancer cells, and occurs comparatively seldom. It is positively known that scirrhous growths may be completely obliterated, but partial healing occurs more frequently.

Czerny makes mention of the fact that carcinoma of the stomach after gastroenterostomy—carcinoma of the rectum after establishing an artificial anus—carcinoma of the breast in women after castration—can be brought to a standstill with partial regression.

Ewing says that spontaneous cure is observed with certain tumors under peculiar conditions. There is a considerable series of polypoid tumors of the skin and mucous membranes where nutrition is cut off by constriction of the pedicle, and such are either completely extruded or regress without detachment. Within the tumor hyaline degeneration of the vessels and mucous degeneration of stroma and parenchyma usually retard growth and may completely exhaust the capacity for growth.

Benign tumors such as exostoses (Nasse, Starck) and papilloma of the bladder (Nitze) have been known to regress. A local or general immunity seems to be the only explanation of an increasing list of spontaneous cures of highly malignant tumors. Most of these cures are only partial; among them are sarcoma, squamous epithelioma and glandular carcinoma (Czerny).

---

*Dr. Edward A. Aronson died on June 24, 1922.

In a consideration of colitis polyposa, Ewing states that the chief seat of intestinal polyposis is the rectum, and the great majority of carcinomas following this condition develop in the rectum or the colon. The ileum or jejunum is rarely affected, but Hauser and Kaufman saw the involvement of the entire mucosa, from the pylorus or cardia to anus, and lesions in the duodenum, jejunum and ileum are reported by Lubarsch, Niemack, Petrow and others. Of thirty-four cases collected by Thorbuke, twenty-three were in the rectum, five in the colon and rectum and six in the colon alone.

Ewing believes that because he finds a diffuse and pronounced hypertrophy of the epithelial lining, a condition arises which is the excessive reaction of the epithelium to irritants. Spontaneous regression has been observed after sidetracking the affected region and after partial excision (Rotter).

Greene (1) reports the case of a physician, aged fifty, who had always enjoyed good health. There had been no history of syphilis nor tuberculosis. The family history was negative except that the patient's paternal grandfather died, probably of carcinoma. About three months before the examination, the patient began to complain of a slight pain in the throat, worse at times when the larynx was in a certain strained position. Examination showed the chest to be negative, there were no glandular enlargements anywhere. There was no cough and hoarseness was very slight. A small growth over the centre of the left cord, about the size and shape of a small grain of wheat, was seen, but pedunculated; the surface appeared uneven and the attached base was distinctly red. Within a week the size of the growth had materially increased and was regarded as a carcinoma. Five months later there was absolutely no sign of the growth. The patient had had no treatment.

Gould (2), in speaking of the cure of cancer, i. e., the disappearance of cancerous growths, said that it, undoubtedly, occurs in animals and is observed in human pathology. It is most frequently seen in the gradual absorption and disappearance of small, secondary nodules in the skin and subcutaneous tissues. Many years before he had shown a patient before the London Clinical Society who recovered spontaneously and completely when she had seemed to be at death's door from cancerous deposits in the lung and neck of the femur, secondary to cancer of the breast.

More recently he had had a woman of fifty-two with advanced cancer of the uterus; the organ was fixed in the pelvis, the cervix ulcerated and masses of the growth were felt invading the anterior wall of the rectum. Three years later the examination of the uterus showed it to be small and senile; the vagina narrowed at its upper end, the cervix small; no ulceration nor growth anywhere; uterus was mobile. The original disease had entirely disappeared.

Another case was that of a trained nurse with a carcinoma of the left breast; amputation of the breast followed. Fifteen months after, a lump was removed from the axilla. Five months later she was operated upon for recurrence in the axilla and skin. She was again operated upon six months later when the axilla was thoroughly cleaned out. This was repeated again after one year and it was found impossible to remove the growth under the arm. The wound healed quietly, the edema of the arm and all evidence of the presence of a growth disappeared. Gould saw this patient again after an interval of ten years and she was enjoying the best of health.

He mentions still another case of a young woman with bilateral carcinoma of the breast, of which later necropsy showed no signs.

He said that cancer even when advanced in degree and of long duration may get better and does sometimes get well. There is cure of cancer apart from operative removal.

Jonathan Wright (3), whose article deals with the microscopic examination of endolaryngeal tumors, says in his introductory remarks, "that there was no doubt that cases of carcinoma existed, which up to a certain period of their growth not only showed the typical clinical picture, but were also diagnosed as such by expert microscopists. Nevertheless, the growth disappeared with or without a radical operation and the patient remained permanently in perfect health. In such cases the clinician or surgeon may possibly doubt his own diagnosis, but is rather more inclined to believe in an error by the microscopist."

Power (4), in a paper on what he describes as vanishing tumors, describes the case of a boy of eight with a cystic lymphangioma of the left side of the neck which was frequently tapped; later he made an excision of a part of it at the posterior angle of the neck. Two months later it was noted that the lower part of the growth was very large and after a period of five months, the boy had several attacks of lymphangitis, after each of which the tumor decreased and finally disappeared.

Koschier (5) believes there is a difference in the virulence of some carcinomata; lymphosarcoma disappears sometimes completely after a minor—certainly an incomplete operation.

Hodenpyl (6) reports the case of a patient, aged thirty-seven at the time, whom he saw with a carcinoma of the breast. The clinical course and morphology of the tumor were typical of a rapidly growing malignant cancer. In spite of radical operation, multiple recurrences appeared in the neck and in the primary scar. At the thorough removal of these, secondary growths appeared which were morphologically typical of rapidly growing carcinoma. Later large tumors developed in the liver which nearly filled the abdominal cavity, followed by the presence of an excessive chyliform ascites. The prognosis was unqualifiedly bad, and the patient's death seemed imminent. Nevertheless, the tumors in the neck and breast dwindled and disappeared. The abdominal tumor gradually grew smaller and became imperceptible while the liver became smoother and smaller. Four years after the operation, the liver was approximately normal in size and position. In the discussion of this case, the writer mentions the development by the patient of some sort of antibody inimical to the growth and persistence of the cancer cells.

The following case of carcinoma of the esophagus has so many unusual points of interest that we feel amply repaid in reporting it.

CASE.—The patient, Mrs. H. B., aged sixty-three, presented herself with the following history: The chief complaint was difficulty in swallowing, duration about six months. Her family history was negative; her husband died of pulmonary tuberculosis; she had had six children, no abortions, menopause at fifty. Past history: typhoid in childhood, at times socalled rheumatism, and had lived in the United States for the past thirty-three years. Present history: six months ago she noted a slight difficulty in swallowing solid food and felt a sensation of constriction at about the jugular fossa; there was no radiation of this sensation. This ceased when food was washed down with a fluid. There was no difficulty in the swallowing of soft foods nor fluids. Appetite was good, with only occasional vomiting. There was no loss of weight. She was a rather rapid eater, drank no tea, moderately of coffee and was of an exceedingly neurotic temperament.

The examination in brief was entirely negative physically, except for the presence of a left femoral hernia. There was no obstruction met in the passage of a stomach tube. She was given a test meal which showed a total acidity of 26 and free hydrochloric acid of 18. The urine was entirely negative.

The fluoroscopic examination at this time showed a narrowing of the middle of the esophagus, with an irregularity at this point. The barium column was arrested at the cardia. There was also some dilatation of the esophagus above the point of arrest. The examination of the stomach was negative except for a marked gastroptosis and a diminished tonicity. At the end of six hours there was no residue. Shortly after this we referred the patient to Dr. Leopold Jaches and we submit his report and x ray illustration.

The röntgen ray examination (fluoroscopic and stereoradiographic) of the chest of Mrs. H. B. showed a marked diffuse dilatation of the aorta, almost aneurysmal in character, and apparently an aneurysm of the innominate artery at its origin. There was a slight deviation of the trachea above its bifurcation, but no constriction, due to the encroachment of the aorta. The lungs and diaphragm failed to show any abnormality. The measurements of the heart on a teleröntgenogram (six feet distance) were: Mr. 3.5 cm.; Ml. 9.4 cm., which is approximately normal. Examination of the esophagus with the aid of a barium mixture showed delay to the passage of the mixture, about three inches above the cardia, and an apparent irregularity which extended from the point of delay downwards for nearly two inches. There was marked retroperistalsis in the esophagus above this area, but no absolute obstruction, so that a spoonful of the barium mixture had to be given before each plate was taken in order to obtain on the röntgenograms the site of the incomplete obstruction and the irregularity below it. Owing to the dilatation of the aorta the indentation to the esophagus at the level of the arch was much more marked than normally. No abnormality was seen in the stomach.

We disagreed with Dr. Jaches in his interpretation of an aneurysm being present and regarded the shadow as described, as being rather a metastatic node with the primary growth in the esophagus.

Realizing that the patient's only chance lay in surgical interference, we referred her to the Mount Sinai Hospital, service of Dr. Howard Lilienthal, hoping that he would be able to apply the operation, as recently described by him (7). This operation was performed on June 23, 1921. On June 16th, i. e., one week before the operation, an esophagoscopy was performed under local anesthesia by Dr. Kaempfer, and he reported that "33 cm. from the teeth there was an obstruction occupying the posterior half of the lumen resembling granulation tissue." A specimen was removed for biopsy and Dr. F. S. Mandelbaum, the pathologist, reported that the specimen showed an inflammation and was insufficient for complete examination. The Wassermann reaction was negative. On June 25, two days after the operation, the patient gave evidence of a very extensive bilateral bronchopneumonia. Her condition was a critical one, and one week later, owing to her weakened condition, she was given a blood transfusion. Two days later, i. e., on July 4th, the patient suddenly went into collapse, the pulse became irregular and respiration finally ceased.

An autopsy was performed and we submit the following report from the pathological laboratory:

"General: Body was that of a fairly well nourished adult female. No petechiæ; no jaundice; no edema, incomplete rigor mortis. There was a large infected gaping wound in the left infrascapular region. There was a resection of the ninth, tenth, eleventh ribs and excision of the intercostal muscles. To the left side of the vertebral column the esophagus was encircled by two rubber tubes and resting on a healthy skin graft, except for eight cm. along the free border. The pleura was exposed and on its external surface there was a thick greenish exudate. There was no communication with the pleural cavity on the right side. The diaphragm was intact. The dome of the diaphragm on the left side reached the fourth intercostal space: The dome of the diaphragm on the right reached the fifth intercostal space. One and a half inches above the bifurcation of the trachea was a globular mass about five by three by two cm. which rested on the trachea compressing it. It was elastic in consistency and on section presented a granular yellowish firm surface having the appearance of carcinoma. In some places, hemorrhage had taken place into the mass.

"The left lung was firmly adherent to the parietal pleura and striped with difficulty. Pulmonary artery and vein were negative. The lower lobe of the left lung showed congestion; lack of aeration, but is not friable. The rest of the left lung and entire right lung were markedly edematous. There were no metastases.

"The pericardial cavity was free of adhesions and contained normal amount of pericardial fluid. The heart was small, flabby and its musculature brown. There were no thrombi in the right auricle. The tricuspid valve admitted three fingers. The papillary muscles were extremely thinned, small, and brownish. The chordæ tendineæ were threadlike. The pulmonary artery was somewhat dilated. The mitral and aortic valves were negative. The aorta had a normal elasticity. The coronary arteries showed small patches of atheroma.

"The mediastinal lymph nodes were moderately enlarged, increased in consistency and black in color. On section they showed no signs of metastases. The bronchi were negative. The trachea at the first thoracic vertebræ showed some flattening. At the level of the fifth thoracic vertebræ there were seen small yellowish excrescences in the mucosa of the esophagus and an area of erosion and hemorrhage. There were no macroscopic evidences of tumor. Thyroid section showed white specks with areas of hemorrhage. Innominate subclavian, common carotid, external and internal carotid arteries were all negative. Due to limited permission, no other organ was examined.

MICROSCOPICAL EXAMINATION.

"The esophagus showed necrosis and ulceration of the mucosa with carcinoma infiltrating the base of the ulcer. Hemorrhage into the necrosis of the wall of the esophagus was present. There were organized thrombi in the vessels. The lung was emphysematous. Mediastinal lymph node showed metastatic squamous cell carcinoma, replacing the entire lymph node with necrosis and pearl formation. The diagnosis was carcinoma of the esophagus, with infection of wound. The cause of death was myocardial insufficiency, metastatic paratracheal growth (carcinoma) causing compression of trachea."

A review of this case presents many interesting facts. First: the comparatively short history. Second: the mild subjective complaint, namely, substernal pressure on swallowing. Third: the irregularity of the esophagus at the point of delay to the barium column, but no absolute obstruction, and the shadow which the röntgenologist regarded as an aneurysm of the innominate artery. Fourth: the absence of any tumor in the esophagus at autopsy, but which before operation may have been an inflammatory mass.

The diagnosis to be discussed, when taking the history and the findings into consideration together with the cancer bearing age of the patient, could very likely be that of a carcinoma of the esophagus. How long this carcinoma had been really present is, naturally, a difficult thing to say; one would have expected that a neoplasm of a fair size could produce this delay to the barium column together with the apparent irregularity in the outline of the esophagus. It was, naturally, a great surprise to find that on autopsy no tumor mass was present, but only the small ulceration which, as the pathologist described, contained cancer cells. It is only a possible, perhaps a probable assumption, that a tumor had been present and the ulcer was merely an ulcer rest. From the onset of the symptoms until her admission into the hospital for operation, there had been no treatment applied to the esophagus.

We first became acquainted with carcinoma of the esophagus when Galen introduced his Tuberculum Carnosum. In the tenth century Avicenna made mention of neoplasma as a cause for dysphagia. Fernel in 1656 and shortly afterwards Coiter first reported carcinoma of the cardia. Sylvius in 1665 also spoke of it. In later years Walshe, Lebert, Köhler described the disease more in detail. Schreiber was able by means of an esophagoscopy to aid in the diagnosis.

Despite the fact that diseases of the esophagus are comparatively uncommon, carcinoma is the most frequent disease affecting this organ. Statistically speaking, it is now an accepted fact that of all carcinomata, carcinoma of the esophagus occupies the fifth place in point of occurrence. As far as the etiology is concerned, we know practically nothing. The most frequent localization is significant of those places where the esophagus is narrowest in a physiological sense, and this is suggestive of the irritative theory put forward by Virchow, because at such points mechanical and chemical factors have most influence. Another etiological consideration is the fact that the esophageal carcinomata may arise in the traction diverticula, together with a simple stenosis and occasionally develop into a dilatation of the esophagus.

Heredity plays no rôle. As a rule carcinoma of the esophagus, as in all carcinomata, is a disease of later life. Heimann observed a case in a patient nineteen years of age. Stuart, one in a twenty-three year old girl; von Hacker, one in a thirty-one year old individual; Kraus, one in a thirty-four year old patient, and one in a thirty-one year old man. From the literature we can conclude that it is of comparatively rare occurrence before the fortieth year, and most cases are observed in the fifth and sixth decades. Curiously enough, males are more frequently affected than females. This is further peculiar because of the larger number of females who succumb to malignancy rather than males.

Metastatic carcinomata involving the esophagus are hardly known. It is in some cases a secondary growth mostly submucous and derived from the lymph passages or the cardiac end of the stomach; more seldom from the pharynx or the thyroid gland. The most frequent neoplasms of the esophagus are the primary ones, and of the squamous epithelial type. Both types may occur in the scirrhous form.

During the course of the disease, stenosis occurs and this is soon followed by dilatation and hypertrophy of the organ above the site of the lesion. As far as localization is concerned, carcinoma may affect any portion of the esophagus, but there are some points of preference, such as those places which show physiological narrowing. In the course of the disease about one half the cases lead either to perforation followed by infiltration into surrounding inflammatory tissues or into contiguous organs.

As far as perforation is concerned, most frequently it occurs into the larger air passages. When inflammatory infiltrations occur, there follows dislocation, displacement of the trachea and larynx with subsequent malignant progress, particularly at the point of bifurcation and more frequently into the left bronchus. These perforations are not necessarily fatal, and may be followed by gangrene of the lung. Perforations may also occur, though less frequently, through the pericardium and be followed by a carcinosis affecting the heart muscle.

There are but few cases described in the literature, and this is probably due to the fact that perforation into the pericardial cavity is most frequently fatal. Some cases have been described where the disease made such progress as to invade the large bloodvessels, and this was followed by thrombosis.

The secondary extension occurs by direct continuity into the stomach or pharynx. The latter occurs very seldom. The extension into the stomach is more frequently seen when the cardia becomes involved. There may be an extension into the mediastinum or the neck. When such an extension occurs into the mediastinum the recurrent nerves and the vagus particularly on the left side, and even the sympathetic can become involved. More infrequently the spinal vertebræ may be affected.

Metastases occur as a rule through the lymph and blood channels. These metastases may be found in the immediate neighborhood; on the pleura, on the pericardium, on the gastric mucosa beyond the cardia and in the esophagus itself. Furthermore, carcinomatous glands may be found, such as esophageal, tracheal, bronchial, at the bifurcation and epigastric. Further metastases may be found in the liver and the lungs.

Metastases from primary carcinoma of esophagus according to Osler (8) are really more frequent than ordinarily supposed. He says: "For many years an impression prevailed that carcinoma of the esophagus had not so great a tendency to form metastases as had carcinomas elsewhere, but this arises from no inherent peculiarity of the growth itself. It probably happened that the secondary growths in the deep cervical glands were often overlooked. It is even more likely that the importance of the structures involved leads to a comparatively early fatal result, at which time the lymphatic involvement and especially extensive involvement of distant organs, is as yet not prominent. The comparatively short duration of carcinoma of the esophagus, compared with that of other sites, is in favor of this explanation. Twelve cases at autopsy in the Royal Victoria series showed secondary growths in eight."

Death usually follows from inanition and cachexia or as a sequel to a perforation.

The clinical importance of carcinoma of the esophagus lies in its effect in producing a narrowing of the esophageal lumen. As a result there are disturbances in swallowing, which may be the first symptom. The dysphagia may follow very slowly. As a result of a diminution in the amount of food intake, emaciation follows. The stenosis may become so marked as to seriously interfere with any food intake.

Carcinoma of the esophagus never runs its course without this accompanying disturbance in the swallowing of food. At times this may be much less than at other times. Apart from this disturbance, severe pain may also be present. This pain has a distinct drawing or tearing character, often referred to the back and referred to the shoulders. It may occur only at a time of eating or may be entirely independent from the time of eating. Among the subjective disturbances hunger and marked thirst may be present.

As far as the diagnosis is concerned, we must rely on x ray esophagoscopy and biopsy.

The duration of the disease is difficult to estimate. It may extend all the way from six months to two years.

We herewith desire to express our thanks to Dr. F. S. Mandlebaum, director of the pathological department, for the many courtesies extended.

Subhepatic Abscess Secondary to Appendicitis*

By PAUL W. ASCHNER, M.D.,
New York,
Adjunct Surgeon, Mount Sinai Hospital.

The various types of abscess complicating acute appendicitis and its postoperative course have received considerable attention from surgeons who have described that common and protean disease. Abscesses occur after removal of the appendix in the following way:

1. They may occur about the appendix stump. The abscesses are intraperitoneal if the stump has not been buried. They are in the cecal wall if the stump has been inverted or buried.
2. They may occur as the localization of an unresolving peritonitis. Such abscesses may be present and overlooked at the primary operation, may develop by extension from the stump region, or as the result of progressive fibrinopurulent peritonitis.
3. They may result from infection spreading by way of the appendicular veins.
4. They may result from extension by way of the lymphatics.

The abscesses are usually described according to their anatomical location. In the cases reported herewith the abscess occupied a position below the right lobe of the liver, in front of the kidney and above the hepatic flexure of the colon. In other words, it occupied the subhepatic fossa or Morison's pouch. Abscesses in this location have been classified inadvisedly, I believe, as subdiaphragmatic.

Barnard, in his excellent addresses on Surgical Aspects of Subphrenic Abscess, defines the latter as any localized collection of pus which is in contact with the under surface of the diaphragm. The under surface of the diaphragm is marked out by the cruciform arrangement of the liver ligaments into four peritoneal fossæ and two extraperitoneal cellular spaces, named as follows:

---

*Presented before Section in Surgery, N. Y. Academy of Medicine, December 1, 1922.

A. Intraperitoneal
  I. Right
    1. Anterior.
    2. Posterior.
  II. Left
    3. Anterior.
    4. Posterior.
B. Extraperitoneal
    5. Right.
    6. Left.

It is the right posterior intraperitoneal fossa with which we are concerned. Barnard describes it as follows:

"It is a pyramidal space transversely disposed beneath the overhanging margin of the liver. Its base and most capacious part rests against the right lateral abdominal wall, projecting just below the last rib. The apex is formed by the upward slope of the margin of the left lobe of the liver. The liver and gallbladder are its anterior boundaries throughout. The posterior wall is divided into a right and left part by the projection forward of the lumbar vertebræ in the middle line. . . .

"Its posterior wall is formed by the upper part of the right kidney, and by the lower part and crus of the diaphragm, and towards the left by the common bile duct and duodenum. It is here that the foramen of Winslow leads into the left posterior intraperitoneal fossa (lesser sac). To the left of the middle line the fossa is a narrow cleft between the right lobe of the liver in front and the small omentum and upper and anterior surface of the stomach behind. Above the subhepatic fossa is bounded on the right by the right lateral ligament of the liver and on the left by the transverse fissure. Below the boundary is formed on the left by adhesions between the margin of the liver and the anterior surface of the stomach, and on the right by similar adhesions of the great omentum and transverse colon to the margin of the liver and the anterior abdominal wall."

Of seventy-six subphrenic abscesses at the London Hospital this fossa contained pus in ten cases and always in association with pus in some other fossa. Six of the ten cases were due to appendicitis.

Lockwood, writing of subdiaphragmatic abscess at the Mayo Clinic, follows Barnard's classification and includes abscesses of the subhepatic fossa.

An examination of the longitudinal section of the thorax and abdomen in the plane of the gallbladder and of transverse sections at the level of the upper third of the right kidney, will show that the subhepatic fossa is practically excluded from contact with the diaphragm and its right crus. The upper pole of the right kidney is uncovered by peritoneum and is in contact with the uncovered area of the liver. The posterior or lower leaf of the coronary ligament is reflected off from the parietal peritoneum covering the middle third of the right kidney. It therefore follows that the right kidney, when normally placed, excludes the subhepatic fossa from contact with the diaphragm. Reference to the diagrams in Cunningham's *Anatomy* will make this point clear.

Sir G. H. Makins, in the *Oxford Surgery,* clearly describes subhepatic abscess complicating appendicitis and advocates the surgical approach which was employed in the cases here reported.

For purposes of diagnosis, prognosis, and treatment subhepatic abscess should be distinguished from subphrenic abscess.

CASE I.—(Hosp. No. 198102.) Mrs. D. V., aged thirty-six, was admitted to Dr. Lilienthal's service January 15, 1920, with a history of sudden onset of abdominal pain the preceding evening accompanied by vomiting, fever, and chills. There was general abdominal tenderness and rigidity of the recti, most marked in the right lower quadrant. At operation free pus was found in the pelvis and along the right lumbar gutter. The appendix was free, gangrenous and perforated. It was removed and tube drains placed in the pelvis and the right lumbar gutter.

Until the fifteenth day the patient's temperature remained below 101° F. Although there had been fascial necrosis, the tube drains were removed and the wound was healing. Now, however, the temperature rose to 102° or 103° F. every afternoon and a search for its cause was begun. The accessory sinuses and lungs were negative. The abdomen was negative except for slight tenderness in the right kidney region. The bladder urine showed pus and Bacillus coli, and therefore pyelitis was suspected. Cystoscopy, however, yielded clear sterile urine from both kidneys.

Tenderness gradually increased in the right renal area and became more marked anteriorly. On February 29th, six weeks after operation, a firm tender mass was palpated just below the liver edge and as this was ballottable into the loin, a perinephric abscess anterior to the kidney was suspected.

On March 1st a four inch incision was made parallel to the twelfth rib, practically the anterior half of the usual kidney incision. The perirenal fat was normal. The peritoneum in front of the kidney was thickened and appeared to overlie an exudate. Aspiration yielded thick pus and on entering the abscess cavity it was found to be intraperitoneal, occupying the space between the under surface of the liver and the hepatic flexure of the colon. The space between the liver and diaphragm was free and clear.

Drainage by tube was established and a rapid convalescence followed. The patient was discharged healed March 19, 1920.

CASE II.—(Hosp. No. 199854.) A. L., a boy of six years, was admitted to Dr. Lilienthal's service March 23, 1920. Nine days before admission he was taken ill with symptoms suggesting influenza. Four days ago abdominal pain, vomiting, fever and constipation appeared. There was general tenderness and rigidity of the recti. A tender pelvic mass was felt by rectum. At operation a diffuse spreading peritonitis due to a perforated appendicitis was found with large collections of pus in the pelvis and right lumbar gutter. Drains were introduced in these situations after the appendix had been removed. On April 1st there was but little discharge and the temperature was reaching normal limits. On April 4th a small tender mass, two inches in diameter, was discovered in the subhepatic area and the temperature was found rising every afternoon. On April 14th the mass had become larger. The blood count showed 22,000 leucocytes, eighty-three per cent. polynuclears. One consultant said the mass represented a normal kidney, but I was convinced that a subhepatic abscess was present. As in the preceding case a three inch incision corresponding to the anterior half of a kidney incision was made. An abscess was found in the subhepatic fossa between the liver and the hepatic flexure of the colon. Although for a time the patient improved in every way, a month later he had to be operated upon for abscess in left lower quadrant, then for a left subphrenic abscess, and finally for a pulmonary abscess of the left lower lobe. After a stormy convalescence, including wound diphtheria, the patient recovered and was discharged healed July 22, 1920. In this case we were dealing with a progressive fibrinopurulent peritonitis.

Case III.—(Hosp. No. 211903.) L. G., a boy aged thirteen, was admitted to Dr. Moschcowitz's service July 20, 1921, with a history of five days' pain in the right lower quadrant of the abdomen, accompanied by fever. There was tenderness, rigidity and a boggy mass in this area. At operation, a retrocecal gangrenous appendix was found with pus in the pelvis. After appendectomy and pelvic drainage the temperature failed to reach normal, and on July 30th rose to 103° F. There were no subjective symptoms but tenderness was elicited in the right upper quadrant. With persistence of temperature, leucocytosis and tenderness, it was decided to explore the subhepatic region.

August 13, 1921. An oblique incision below the twelfth rib was made (as in the preceding cases). The perirenal fat was normal. On opening the peritoneum in front of the kidney, numerous filmy adhesions of the colon to the liver presented, but no pus was found. On separating these adhesions working upward and backward along the under surface of the liver an abscess was entered which extended behind the liver. It could not be determined whether the process began intraperitoneally or as a lymphatic infection of the retrohepatic cellular tissue (in which case it would be a subphrenic abscess). Excellent drainage was obtained by the approach employed. Healing was complete on September 2nd.

In the following case a subhepatic exudate developed which either resolved or ruptured into the bowel. No operative interference was necessary.

Case IV.—(Hosp. No. 215,084.) M. L., male, aged twenty-three years, was admitted to Dr. Moschcowitz's service November 19, 1921, with four days' history of abdominal pain, localizing to the right lower quadrant. The lower abdomen was rigid and tenderness was most marked at McBurney's point. At operation a gangrenous appendix was removed and a drain placed to the pelvis because of beginning peritonitis. Temperature was normal by the fifth day, but on the twelfth day it rose to 101° F. and thereafter daily to 102°. Tenderness in the right hypochondrium and right costovertebral angle was elicited and on December 5th the leucocytes were 30,400, eighty per cent. polymorphonuclears. A distinct tender mass was detected deep in the right hypochondrium. On December 10th the temperature dropped to normal. The rigidity and tenderness of the right upper abdomen rapidly disappeared, and the mass became more easily palpable, but no longer tender. By December 22nd, the leucocytes were 12,400, fifty-four per cent. polymorphonuclears, and the mass had completely disappeared. It appeared that the exudate had undergone resolution, or spontaneous drainage into the bowel.

A patient operated upon for appendicitis with more or less peritonitis, and presenting the usual postoperative improvement for one or two weeks, manifests afternoon fever and polymorphonuclear leucocytosis without other subjective symptoms. Physical examination at first reveals no localizing signs but sooner or later deep tenderness is elicited in the right upper quadrant just at or below the liver edge. A mass is finally detected deep in the subhepatic area and tenderness in the tenth and eleventh right intercostal spaces, and in the costovertebral angle. The mass may be ballotable into the loin and suppuration of or about the kidney is suspected. There are no evidances of irritation of the diaphragm nor of impaired aeration of the right lung. The grave signs of toxemia in subphrenic abscess are usually absent.

With the onset of remittent or intermittent fever; and with no subjective or objective symptoms to indicate the true lesion, wound retention, subphrenic infection, hepatic abscess or beginning pylephlebitis are considered as possibilities. Then as tenderness appears below the liver edge, or in the costovertebral angle, one begins to suspect the kidney, and the urine may confirm that suspicion by coincidence. Finally when a mass becomes palpable in the right renal area a perinephric abscess in front of the kidney, or an abscess of the kidney itself, cannot be excluded with certainty, as cystoscopic examination is usually completely negative in perirenal suppuration and cortical abscess.

While the diagnostic difficulties are considerable in patients recently operated upon for appendicitis, they are much greater when, because of the location of the appendix, a subhepatic abscess presents as the primary condition.

The inflammatory exudate may occasionally resolve. If suppuration supervenes the abscess may rarely drain itself by breaking into the bowel. As a rule surgical drainage is indicated, and the approach should be made through a loin incision which permits of adequate exposure of the organs and spaces under suspicion, without risk of soiling the general peritoneal cavity.

As already indicated subhepatic abscess occurs, as a rule, in patients who show more or less spreading peritonitis at the primary operation, and the prognosis would naturally vary with the extent of the peritonitis and the patient's ability to localize it. When the subhepatic fossa becomes infected from the right anterior subphrenic space as in Barnard's cases the prognosis is dependent upon that of the subphrenic infection.

It is apparent from the position of the abscess that it is walled off by the liver and kidney from the vulnerable diaphragm and pleura, while the omentum and colon protect the general peritoneal cavity. A well localized suppurative focus such as this offers a good prognosis if it is recognized early and drained by the proper route.

For anatomical and clinical reasons subhepatic abscess should be distinguished from subphrenic abscess. The best surgical approach is through the loin by an incision corresponding to the anterior part of the usual kidney incision.

The Rôle of Bacillus Welchii in Gangrenous Appendicitis*

And the Use of the Antitoxin of Bull and Pritchett in Its Treatment

By JOHN E. JENNINGS, M.D., F.A.C.S.,
Brooklyn,
Surgeon, Brooklyn Hospital.

Before the war we had noted a few isolated cases of peritonitis following gangrenous appendicitis in which it was evident that Welch's bacillus was a pathogenic factor. Some of them were associated with retroperitoneal edema of rather marked degree. Some were attended with gangrene of the abdominal wall. All were highly toxic and all were fatal. We had become convinced that the clinical picture of the local lesions was more or less characteristic and in a few cases we were able to anticipate the presence of the Bacillus aerogenes capsulatus, which cultivation and animal inoculation afterward verified.

We considered, at that time, however, that these were rather rare infections. We had no therapeutic measures with which to combat the inevitably fatal issue and the difficulties of routine anaerobic bacteriological study hampered further investigation. The studies of gas gangrene made during the war and the notable work of Bull and Pritchett with their preparation of an antitoxin were in mind when we returned to civil practice.

During the winter of 1919 and 1920 a series of gas gangrene infections occurring in my service at the Brooklyn Hospital, which I shall report elsewhere, led us to the use of a mixed perfringens and tetanus antitoxin, the only one available. Its striking success in these cases suggested the consideration of its possible value in cases of gangrenous appendicitis, with spreading peritonitis, and led us to the study of the rôle of the Bacillus Welchii in the course of that disease. Our brief experience in the course of that study has seemed sufficiently interesting to warrant this preliminary report. A study of the rather rich literature on the Bacillus Welchii shows a surprising poverty in studies directed toward one of its more obvious spheres of action.

Welch records thirteen cases of diffuse peritonitis in which Bacillus Welchii was found. Ten of these were perforative and three nonperforative cases and he also notes the presence in two cases of circumscribed gas containing intraperitoneal abscesses resulting from perforation of the appendix vermiformis.

Flexner made cultures at various times postmortem, from sixty cases of endogenous peritonitis, and found Bacillus Welchii in eight cases, usually in mixed cultures. His work done in 1898 seems quite primitive and not at all complete.

Wright and Stokes isolated the organism in pure culture from peritonitis complicating typhoid as did also Hitschmann and Lindenthal and Von Hibler and a number of other observers have found it in cases of peritonitis of various types.

Veillon and Zuber made a valuable contribution in which they first definitely noted the presence of Bacillus Welchii, which they called Bacillus perfringens, in infections of the appendix. Their conclusions are worth translating and transcribing. The suppurative infections of the appendix in which the organ is gangrenous, perforated or on the point of being so, in which the pus has a markedly fetid odor, contain in abundance anaerobic microorganisms which we have been able to isolate and describe. When they contain streptococci and colon bacilli, which is not absolutely constant, these latter organisms are always present in infinitesimal quantity in proportion to the others.

Dudgeon and Sargent made a study of the bacteriology of appendicitis in England in 1905 in which they came to the conclusion that the Bacillus coli was the most frequent cause. They did not believe that anaerobic bacteria played any important rôle in appendicitis or peritonitis. They believed that if Bacillus Welchii was frequently present in cases of appendicitis, emphysematous gangrene of the bowel should be a common lesion instead of an interesting curiosity and that foaming viscera should be seen very frequently at autopsies on patients dead from appendicitis. Instead there was only one case of foaming organs in such cases among the autopsies at St. Thomas's Hospital in one year, 1905. They found themselves quite unable to grow streptococci but cultivated staphylococci and pyocyaneus with their colon bacilli. Their work would be negligible were it not that it would seem to have diverted attention from the study of the significance of the anaerobes in this disease, being quoted by Simonds in 1915 as the last word on the subject.

On the other hand, Lanz and Tavel found in 138 cases of appendicitis Bacillus edematis maligni in forty-nine, classing under Bacillus edematis maligni various anaerobes including Bacillus Welchii.

Runeberg in 1908 found Bacillus Welchii once in fourteen cases of appendicitis. He believed that anaerobes played an important part in appendicitis and peritonitis by the production of toxins rather than by actually taking part in the infection.

Heyde of Friedrich's Clinic in Marburg in 1911 published a monograph on the anaerobes in appendicitis. He concluded that anaerobic bacteria were present in one hundred out of 102 cases studied and that they were present in greater profusion than aerobes in all stages of appendicitis and peritonitis and attributed to them the direct causation of inflammation, of gangrene and of toxemia. He found that the perfrigens group (Bacillus Welchii) outstripped all others in rapidity of growth.

Grigoroff studied eighteen normal and thirty-one diseased appendices. In the normal appendices, aerobes and anaerobic specimens were present in approximately equal proportions or aerobic organisms were more abundant. In the inflamed appendices, however, the strictly anaerobic bacteria were strikingly predominant. In the thirty-one cases of appendicitis, Bacillus perfringens (Bacillus Welchii) was found nine times.

---

*From the Surgical Service, Brooklyn Hospital.

Simonds, in his classical monograph, Studies on Bacillus Welchii with Special Reference to Classification and to Its Relation to Diarrhea, noted in 1915 that the relation of anaerobes in general and of Bacillus Welchii in particular, to appendicitis is still unsettled. He found Bacillus Welchii in the sporulating form in pus from an appendix abscess and found spores of Bacillus Welchii in ninety per cent. of normal appendices obtained at autopsy. They were present in approximately one hundred per cent. if the appendix contained fecal matter. He attributed to Hitschmann and Lindenthal the statement that Bacillus Welchii never forms spores in tissues in which it is playing a pathogenic part and remarked that it is possible therefore, if spores of Bacillus Welchii are present in appendiceal pus, that its presence is only accidental and not in any way connected etiologically with the infection.

Our problem seemed to be briefly this—the Bacillus Welchii is a normal inhabitant of the gut in man. It, with other anaerobes, produces gangrene in simple and mixed infection. We have seen cases of peritonitis in which infection with this was the apparent cause of death. We have in our possession an antitoxin which proved its usefulness in infection by the Bacillus Welchii elsewhere. Is this serum useful in appendicitis and if so how?

Our investigations may be grouped as follows:

1. Bacteriological studies of the contents of the appendices removed at operation.
2. Bacteriological studies of specimens of tissue from the wall of oppendices removed at operation without invasion of the lumen.
3. Bacteriological studies of the fluid removed from cases of peritonitis secondary to gangrenous appendicitis.
4. Bacteriological studies of the blood in cases of Bacillus Welchii infection.
5. Postmortem studies in cases of death due to peritonitis and appendicitis.
6. Clinical studies of the usefulness of perfringens antitoxin in cases proved by culture, infections with Bacillus Welchii.

I shall discuss briefly the results of each of these groups of study. Simonds notes that he found Bacillus Welchii in the sporulating form in pus from an appendix from the clinic of J. E. Thompson, and that he found spores of Bacillus Welchii in ninety per cent. of normal appendices removed at autopsy. They were present in approximately one hundred per cent. if the appendix contained fecal matter. Our experiments agreed with this. Cultures taken from the lumen of the appendices removed at operation, whether acutely inflamed or not, showed in ninety per cent. of the cases a positive culture of Bacillus Welchii.

In seven cases in which the appendix was acutely inflamed, thickened and edematous, but with no gross perforation, cultures made of portions aseptically removed in the operating room and so cut as to remove the peritoneal and muscular coats of the organ without invading its lumen, also showed the presence of Bacillus Welchii.

In sixteen cases localized pus collections with gangrene showed Bacillus Welchii and in forty cases in cultures made from free fluid in the pelvis or general peritoneal cavity Bacillus Welchi was found ten times.

The results of blood cultures were for the most part negative. The studies of the blood made in cases of gas gangrene during the war, showed that blood culture is negative at the beginning of gangrene. In cases fully developed, Lardonois and Baumel found seven positive cases in forty-eight cultures. Weinberg and Seguin found four positive cultures before death in twenty cases of hemoculture. Delbet and Fiessinger found two positive in seven blood cultures made in the agonal period. It is evidently the general opinion that the passage of organisms into the blood occurs just before or after death, as the antitryptic index and alkalinity are lowered.

It is evident that Bacillus Welchii is present in the lumen of most appendices and is frequently found outside of the lumen of the gut in an actively growing form in appendicular abscess and in localized peritonitis and in a rather large number of cases in free peritoneal exudate. That in most cases its activity is cut short by operation with removal of the appendix and adequate drainage. This, however, is not always the case and it is apparently an active factor, if not the most active factor in the production of a fatal issue.

In the fatal cases that we have been able to study, the Bacillus Welchii has been present with a large amount of peritoneal exudate, in some cases generalized and in others walled off.

In the beginning of our studies we were handicapped by the fact that culture, made at the time of operation, required from twelve to twenty-four hours for an available report. We found, however, that by making injections of the suspected material in the liver of the living guineapig, killing the animal at the end of three minutes after the injection, placing the animal in the incubator, making a section of the animal at the end of two hours with study of the liver, was an adequate clinical test. This method we have checked by guineapig controls and by milk cultures of material made at the same time. It places a bacteriological diagnosis of the presence of Bacillus Welchii within range of clinical usefulness and will be reported more fully in another communication.

After we had satisfied ourselves that the Bacillus Welchii was a factor we began to inject an immunizing dose of the perfringens serum as a routine in cases of gangrenous appendicitis with spreading peritonitis. In one case, 577-22, in which this was done, there developed an active, general peritonitis from which the patient died. Welch's bacillus being isolated in large numbers from his peritoneal exudate and from his heart's blood immediately postmortem. Since that time it has seemed desirable to make the injections intravenous when indication for its use is found.

The margin, with use of the serum in appendicular peritonitis, is not very wide. The diagnosis of the presence of the organism must be promptly made. The use of the serum must be equally prompt. It must be given intravenously. The doses should be liberal and should be repeated before evidences of profound intoxication have made their appearance.

Occasions in which we have used the serum fall into three groups:

1. Those in which its use is unavailing. The failure in these cases is due to: a. an inadequate dose, b. administration too late.

2. Cases in which an early administration of the serum, with absence of severe clinical symptoms, leaves room for discussion as to the necessity of its administration at all. This is the ideal use of any antitoxin. It is the way in which diphtheria and tetanus antitoxin are most ideally used. It is the ideal way for the use of this one.
3. Cases in which the indication, both bacteriological and clinical is unmistakable and in which liberal use of the serum was attended with striking success.

I shall report a few cases from each of these groups. In seven patients dying of appendicular peritonitis in my service in the last two years, five showed positive cultures of Bacillus Welchii; in two cases the cultures were negative and in one no culture was taken.

Case I.—In the positive cases, one, 577-22, showed Bacillus Welchii at operation with a moderately severe, generalized peritonitis, was drained with appendectomy, in the usual manner and given twenty c. c. of serum subcutaneously, a dose which proved inadequate. Distention and vomiting developed on the second day postoperative. The patient's pulse was imperceptible for seven hours before death. His temperature remaining below 100° F. and consciousness persisting to the last twenty minutes. Death occurred four days postoperative. The picture, so characteristic of peritonitis, is identical with the classical descriptions of death due to gas bacillus poisoning from gunshot wounds of the extremities.

Case II.—739-22, a child of five years, showed general diffuse peritonitis of seventy-three hours' duration with cyanosis, distention, feeble and thready pulse. At operation, free turbid fluid in the peritoneal cavity, a leaking abscess. Appendix showed terminal gangrene with a small perforation. One hundred c. c. of perfringens antitoxin was given on the operating table. Six hours after operation the radial pulse was imperceptible and more serum was given, 150 c. c. in the vein, 200 c. c. in the axilla following which the patient rallied. A few hours later another collapse was controlled by more serum. Altogether 970 c. c. of antitoxin were given, most of it intravenously. The patient rallying after each administration. Seven days after operation lobar pneumonia developed. In the meantime the abdominal distention continued extreme and never yielded to treatment. On the eleventh day the pulse became imperceptible, the hands cold and clammy, lips cyanotic, distention extreme, respiration labored, conscious till the last. Guineapig culture was positive. At autopsy the last twelve inches of the ileum were found gangrenous and adherent to the pelvic wall causing a complete intestinal obstruction. The general peritonitis had subsided but the local gangrenous process had gone on.

It has been our experience that the use of antitoxin does not affect the growth of the organism in the wound discharges nor in the tissues of the abdominal wall.

The only hope for recovery in this case lay in the recognition of the obstruction and operative relief, which, with the added burden of a pneumonia, she could hardly have borne. It is evident that the germ was especially virulent and that not only the appendix but the entire lower ileum was affected by the gangrenous process as it so often is in a suppurative one. The antitoxin prolonged life sufficiently to allow the development of this unusual condition.

Case III.—The next (3241-22) case showed an old abscess, three weeks old, with previous attacks, and many old adhesions, causing partial obstruction. The dissection of the abscess and liberation of the ileum, initiated a peritonitis which proved fatal. The Welch bacillus was recovered from the drain and 200 c. c. of the serum were given intravenously, forty-eight hours after operation, without material effect. In this case, as in the preceding one, the terminal collapse was sudden. The administration of antitoxin was late and inadequate. In a similar case I should now use a larger dose and give it sooner.

Case IV.—1805-22, man, forty-seven years of age. Vomiting and pain in the abdomen for twelve days before his admission. A large mass in the lower abdomen, the size of a grapefruit, near the midline was found. At operation the whole lower abdomen was filled by an inflammatory mass which involved the intestines and seemed to originate, from its position and nature and extensive amount of pus, from a ruptured appendix. Finger dissection, opened into the mass. About one quart of very foul smelling, thin pus was obtained. Counter incision made into the left inguinal region in which a rubber drain with iodoform gauze in it was inserted, two rubber tubes to the appendix region and pelvis. The appendix was not found. Caprolith was in cavity. Bacillus Welchii was reported in the pus from the cavity. Five hundred c. c. of serum given thirty hours after operation, 200 c. c. given twelve hours later and 100 c. c. of serum given twelve hours after the second injection. There was a tremendously severe intoxication. Serum injection was followed by temporary improvement. Failure to hold this resulted in collapse and death. The patient should have had serum earlier, more serum and more frequently.

Case V.—3826-22. The patient came to us late in the course of a peritonitis. He had a large amount of free, turbid fluid in the general peritoneal cavity with a partial wallingoff, by omental adhesions, in the pelvis. He took the anesthetic badly and left the table with a great deal of froth in his throat. An immediate guineapig culture gave positive result for Bacillus Welchii and 100 c. c. of antitoxin were given in the vein. For twenty-four hours he did well and his peritonitis seemed under control but on his second day pneumonia developed and the patient died, with edema of the lungs.

In the other three cases no serum was used nor was the Welch bacillus recognized as being present. They may therefore be ignored in this discussion.

The second group of cases is that in which an early administration of antitoxin was followed by recovery and the suggestion that they probably would have recovered without its use. This, as I have said, is the way to use an antitoxin of any kind. No apology is therefore given for its use in these cases. The only question in my mind is how much to give and what is the earliest indication.

We have had fourteen such cases with suppurative, gangrenous appendicitis and established diffuse peritonitis, in whom the presence of Bacillus Welchii has been recognized and an immediate injection of antitoxin given. Most of these patients, evidently sick enough at the time of operation, have had a chill and serum reaction an hour or two after the injection and have then proceeded to recovery.

The third group consists of patients in which the administration of serum to desperately sick patients, which proved Welch's bacillus infection, has been followed by dramatic and brilliant results.

In this third group several cases seem worthy of more or less detailed report.

Case VI.—1811-22, a strong man of twenty-six years of age, traveling salesman, had right lower quadrant pain for thirty-six hours with vomiting, distention beginning, abdomen still boardlike, cyanosis and dilated pupils, pulse thin and running. Operation disclosed free fluid, pus not foul, appendix gangrenous, surrounded by foul abscess, leaking. Five hundred c. c. of antitoxin was given on the table and 200 c. c. given twice during the first three days after operation, which were stormy. The effect of an intravenous injection of antitoxin was noticeable in this case, as it was in Case II. The cyanosis disappeared. The pulse improved and slowed and the whole appearance was altered for the better. He took 900 c. c. of serum and made a good recovery. Curiously, in his second week an axillary abscess appeared at the site of a hypodermoclysis, from which Bacillus Welchii was isolated in pure culture. There was no crepitation nor gas formation. The skin was somewhat bronzed. The blood was repeatedly negative.

Case IX.—2842-22, a girl aged seventeen. Seventy-two hours after the onset there was general rigidity with beginning distention. At operation, free, turbid blood stained fluid in the peritoneum was found. There was a large mass the size of a croquet ball, flattened against the pelvic wall, half above and half below the brim, with the omentum adherent over the mass. The pelvis was full of turbid seropus. The appendix was gangrenous at its middle, and removed with the adherent mass of gangrenous omentum. A drain to the pelvis was inserted. Guineapig culture in two hours. Two hundred c. c. perfringens serum was given. There was a good recovery with long draining abscess cavity.

Case X.—4875-22, showed another leaking abscess. The patient was a young woman of twenty-two, telephone operator. Operation was done ninety-six hours after onset. The retroperitoneal tissues and peritoneum were injected, the peritoneal cavity containing a large amount of straw colored fluid, small intestine slightly injected, cecum normal. A mass was discovered the size of a tennis ball, tense, and riding above the pelvic brim, just below the anterior superior spine. The omentum was adherent. The mass was covered with lemon false membrane. A drain to the pelvis and to the appendix stump was inserted. The guineapig was positive for Bacillus Welchii in two hours. Two hundred c. c. perfringens serum was immediately given with 200 c. c. saline solution in the vein. The recovery was prompt and free from complications.

The mortality in gangrenous appendicitis is by no means as low as one would like to think, as may be seen by anyone who cares to study the tabulated causes of death shown in the weekly reports made by the Health Department of the City of New York.

The ideal time of removal in suppurative appendicitis is before gangrene has occurred. The removal of a gangrenous appendix, with proper drainage and aftertreatment, results, in a large number of cases, in recovery. In a certain number of cases, however, death occurs and it is apparent that a certain proportion of those, how many we cannot say, are due to the activity of the Bacillus Welchii.

The evidences of intoxication due to the Bacillus Welchii, in the peritoneal cavity, are insidious in their onset and do not differ from those which have been associated with septic peritonitis for many years. There may or may not be a rise in temperature. The pulse frequently rises, cyanosis in some degree is an early sign and increases with the severity of the case. As the case advances the pupils dilate, the skin becomes cold and clammy, the pulse becomes thready, feeble and impalpable. Consciousness is frequently unimpaired until the last or a short period of delirium may occur. The cyanosis now becomes extreme and death supervenes.

It seems probable that the Bacillus Welchii infection in appendicitis occurs, as a rule, in symbiosis with a number of other organisms. The streptococcus and Bacillus coli, as well as other organisms, are present. Just what the relation of these organisms is to the disease and to each other remains a field for study but in the possession of a potent antitoxin to the Welch bacillus we have another weapon which should not be longer ignored.

Our present position with regard to its use is as follows:

1. At the time of operation in a case of appendicitis with localized, spreading, general peritonitis, culture and guineapig inoculation should be made at the time. The report from the animal will be available in two hours. The culture will be available, for verification, in from twelve to twenty-four hours. If the animal shows the presence of Bacillus Welchii, intravenous injection of from one hundred to two hundred c. c. should be immediately given (in certain cases of spreading peritonitis a smear from the peritoneal fluid will show the presence of encapsulated bacilli, recognizable as morphologically Bacillus Welchii, in such cases even two hours wait before injection is unjustifiable.

2. From twelve to twenty-four hours is a suitable interval for further injection of one hundred c. c. The clinical response, in cases showing rapid pulse and cyanosis, is well marked, the pulse slows and improves in quality, the cyanosis disappears and the patient's general morale noticeably improves. In active cases of diffuse peritonitis the serum should be used in massive and repeated doses, and it is of course to be emphasized that in no way should the antitoxin be used to supplant the surgical measures already at our command nor to favor delay in operative treatment.

It will be evident that the use of the antitoxin in intestinal obstruction and as a prophylactic in gunshot wounds of the bowel and in operations on the intestinal tract must suggest itself. We have had some few interesting experiences with its use in these conditions as well as in infection of the genital tract in the female and genitourinary tract in the male and the gallbladder. I shall report these in a later paper but wish to emphasize the opinion that the relation of this organism to gastrointestinal pathology well deserves further careful study.

Reports of Cases VII and VIII will appear in the author's reprints.

The Diagnosis of Appendicitis

By LOUIS DROSIN, M.D.,
New York.

Notwithstanding the frequent occurrence of appendicitis and in spite of its many signs and symptoms, a correct diagnosis is still conjectural and in many cases it is impossible. This is particularly true in chronic cases. Unless the physician has himself observed a typical acute attack he frequently has to accept the patient's word for its previous occurrence.

There are many methods of examination now in use, and many more that have been temporarily regarded as entirely determinative but which have eventually fallen into disrepute. Among these is McBurney's point. "It is no longer to be depended upon" (1). Almost all the signs and symptoms of appendicitis are common to many other pathological conditions. This statement holds true for even the most important of these signs—localized pain and tenderness with or without rigidity in the right iliac fossa, or, to be more correct, in the region of the right iliac fossa.

This sign can be produced by other causes, yet it remains the most reliable, the most important and the most constant. When we can elicit this sign and exclude other conditions which might cause it, we are almost safe in our conclusion that the case is one of appendicitis.

In recurrent appendicitis, however, in which the patients have had a number of typical attacks, unless some inflammatory condition remains or adhesions have formed, it is impossible to elicit pain or tenderness even though noninflammatory pathological changes are present. Should some trace of inflammation remain, or adhesions form, then the characteristic localized pain, or tenderness, can be brought out. This may be accomplished by the following methods which I have found reliable in a large number of cases. They were corroborated by dependable previous histories or by operation:

1. With the patient lying on the back, the knees either flexed or extended (both postures should be tried), place two or three fingers of the examining hand on the abdomen or near it, to the right of a line midway between the umbilicus and the ensiform cartilage. At the end of an expiration give a sudden thrust backward. In very acute cases this thrust should be moderate. If inflammation or adhesions are present and unless it is very low down, retrocecal, or adhesions are absent, the patients will experience a sensation at the seat of the trouble which they variously describe as a pull, a turn, a twist, a jar, or a knock. They sometimes feel a mild pain in the region of the appendix, but never a severe pain even though the case be acute.

This procedure can be repeated but a few times, especially if the thrust causes pain or shock on the spot where the thrust is made. The reason for this is that the patient will very quickly anticipate the action and will voluntarily or involuntarily resist by holding his breath or by contracting the abdominal muscles. This sign is present in postoperative adhesions also. The result is undoubtedly obtained by the direct or indirect jar or pull on the cecum and appendix, on adhesions, or on all combined, through the colon and disturbance of its contents. It is probably assisted also by the reversed peristalsis present in the ascending colon.

2. With the patient lying in the Sims position, on the right side, his back preferably toward the examiner, no pillows under the head, the abdominal muscles will be relaxed and the cecum and appendix brought upward and forward so as to come readily into the palpating hand. Press the tips or the palmar surfaces of the fingers backward, systematically covering the whole ileocecal region until the painful spot is encountered. In some patients the same result can be obtained in the simple lateral position, on the right side, with legs flexed.

3. The patient lies on his back, left leg extended and right leg flexed so that the thigh and abdomen will form a right angle, or approximately one, the thigh being supported by the arm and elbow, two or three inches below the knee (behind the thigh), knee relaxed and leg hanging loosely in the air. In this position the appendix and cecum are brought upward and forward, as well as toward the median line. The rectus muscle is relaxed, and real rigidity, if present, is made out. If rigidity is brought on by the patient's fear, this is easily eliminated. The ileocecal region and adjacent area can then be palpated and pathological conditions of the appendix or cecum can be defined.

That this method of palpation and the Sims posture do bring the cecum and appendix upward, forward and sometimes to the median line is proved by this fact: not only can the morbid condition be located with facility, but the position of the pain will be higher and more to the centre than when felt in the usual posture for abdominal examination. If in this latter (the usual) posture, where both legs are either flexed or extended, the pain can also be localized, then we have further proof, by comparsion, that these positions bring the cecum and appendix upward, forward and to the median line.

4. During a prolonged interval between an expiration and an inspiration the abdomen, as a rule, is completely relaxed. If during this interval pressure is applied, independently or in combination with the methods outlined above, it will be found useful in eliciting the sign of localized pain. Some abdominal walls are so relaxed that the patient can be examined satisfactorily regardless of expiration. But whatever the degree of relaxation, more definite and accurate information may be obtained by bimanual and bilateral pressure—the simultaneous use of both hands. The palmar surfaces of the fingers of each hand occupy a corresponding area over the abdominal wall, and in this way the surface of the involved field may be covered. As the pressure is even and the examination simultaneous the information derived from this method is more trustworthy than when one hand is used alternately for comparison of each half of the abdomen. This is best carried out with the examiner between the patient's knees or thighs.

The methods I have been describing are not applicable in acute and chronic cases of appendicitis alone. They are useful in other pathological conditions of the abdomen. In my experience, tuboovarian diseases with all their variations always require bimanual (combined intravaginal and abdominal) examination for a diagnosis. Even where these patients experience pain as a subjective symptom (unless peritoneal irritation or peritonitis is present), tuboovarian troubles are rarely affected, aggravated or located by external abdominal pressure examination alone.

Bassler (1) has pointed out that although in most individuals the appendix is usually situated at an identical point in the cecum, yet the cecum differs widely in situation. Its position varies from a rather high level in the iliac fossa to "perhaps well over the brim of the pelvis, even as far as the median line. This change represents a curve of practically five inches in length—the appendix in different individuals is situated anywhere between the two ends." By percussing out the limits of the cecum the appendix may be more readily located and any localized pain may then be elicited by the methods I have described.

In closing my paper I wish to give a brief description of a case of more than usual interest to the profession. It will illustrate that appendicitis even with an abscess may resolve without leaving subjective symptoms, and, unless the x ray might show it, without objective symptoms also.

Case I.—The patient, a man about forty years of age, a baker by occupation, came under my observation about two years ago. He was married, had several children, and was in very poor circumstances—if that fact had any bearing on the case. He had an abscess the size of a large egg, easily palpable and almost visible, in the right iliac fossa. His temperature by mouth was 102° F. He neither looked nor acted like a very sick man; there was nothing in his appearance to indicate the extent and gravity of his pathological condition. I advised an immediate operation but he refused this, giving as a reason that he was afraid. I explained to him that unless he had the operation, he would die. He then told me the following story: He had been a patient at the Flower Hospital and was to have been operated on for appendicitis by Dr. A. A. Berg. Although the patient was actually on the operating table, fear overcame him and he got off and went home. He was willing now, he said, to return to the hospital but was afraid that Dr. Berg would refuse to take care of him. I immediately reassured the patient, promising to speak personally to Dr. Berg as I was confident he would not refuse.

In a telephone conversation with Dr. Berg I reminded him of the case and was then told that this man had walked off the operating table not once, but twice, and furthermore, since the patient left the hospital another physician than myself had previously called him up to the same effect. Dr. Berg expressed himself as being entirely willing to take care again of the patient on the following conditions: that I personally make the arrangements for his readmission and that when he entered the hospital again Dr. Berg would come to see him. I made the arrangements, but the patient failed to come in.

Several weeks later I met the person upon whose advice the man had first come to me ,and I was told that the patient, instead of going to any hospital at all, had remained in bed for about three weeks and that he was now perfectly well. I told my informant that I would consider it a personal favor if he would send the man to me for an examination. A short time afterward the patient presented himself at my office looking hale and hearty. I then made a thorough and prolonged examination which revealed nothing whatever. I have subsequently made three other examinations and, in each instance, with the same negative results.

In the recurrent form of appendicitis, periods of perfect health do separate the acute attacks, although the textbooks doubt that such attacks ever run their course to recovery leaving a perfectly healthy appendix, pathologically considered" (1). The case I have been describing had reached the point at which spontaneous recovery rarely occurs and it would be interesting to know by what means recovery was brought about and to what extent pathological conditions would still be found existing in the appendix.

SUMMARY AND CONCLUSIONS.

Although appendicitis is of the most frequent occurrence and has many symptomatic signs, it is often difficult and sometimes impossible to diagnose it. The most important and most constant of these signs is tenderness and localized pain. In recurrent appendicitis it is difficult to elicit the pain when the examination is made with the patient lying in the usual posture and when unimanual pressure is the method employed in palpation.

There are four different postures in which it is possible to bring out the location of pain if combined with a special method of eliciting the pain.

In the first method a sudden backward thrust is given from the examining fingers to the right of a line between the umbilicus and the ensiform cartilage. The pain elicited will be mild even if the case is acute. Usually no pain is felt, but a shock described as a twist or other mechanical effect. This is especially symptomatic of adhesions.

The second position is the Sims with the patient lying on his right side. This posture brings the cecum and appendix upward and forward into the palpating hand, the tips and palmar surfaces of which are employed for pressure.

In the third position the patient lies on the back with the right leg supported under the knee (left extended), which also brings the cecum and appendix upward and forward and tenderness or rigidity may be made out if present.

In the fourth method, during a relaxed state of the abdominal walls between expiration and inspiration, bimanual pressure over both sides of the abdomen will give diagnostic information.

The usual postures in examination by the usual method for diagnostic signs in appendicitis do not always elicit pain.

New combinations of posture and pressure methods successfully elicit pain where any trace of inflammation or adhesions remain.

Value and Limitations of the X Ray in the Diagnosis of Chronic Appendicitis*

By LESTER LEVYN, M.D., F.A.C.P.,
Buffalo, N. Y.

The evolution of the röntgen method has been so rapid in the last few years that it is at the present time one of the most efficient if not the most valuable single method of procedure in diagnostic achievement. This fact, however, is not sufficient reason to abandon other recognized means within our armamentarium. The patient who presents himself for examination should be given the benefit of not one but a combination of all the available methods whereby the percentage of error in diagnosis may be reduced to a minimum.

Frequently I am confronted by my medical and surgical confrères with the statement that the x ray rarely makes the diagnosis of chronic appendicitis which has not been previously established by clinical methods, that it is only of confirmatory value. If its usefulness were limited even to that extent its place would be firmly fixed. Knowing that often symptoms of chronic appendicitis are obscure and may produce their effects reflexly such as nausea, vomiting, vertigo, pylorospasm, hypersecretion and epigastric pain, I hope to show wherein knowledge is placed at our disposal concerning the appendix which we were quite unacquainted with in preröntgen days.

It might be of interest to state that Cignozzi of Naples in January, 1922, reported that "in five hundred surgical treatments for appendicitis, he had been able to observe in adolescents a particular clinical form of appendicitis whose objective symptomatology is marked by general nutritive dystrophia, an arrest of development and phenomena of infantilism. The histories and the subjective and objective disturbances would tend to show that it is the appendicitis lesion that brings about this condition of faulty nutrition and of arrest of development. In fact, appendectomy brings about the cessation of local disturbances and an immediate change in the organism in the direction of a normal somatic and genital development. The therapeutic criterion demonstrates absolutely the connection between cecoappendicular changes and general dystrophia because cure inevitably follows removal of the appendix." In so far as many of these changes can be observed only by means of their actual demonstration under the screen, many cases of dystrophia and infantilism could be prevented by the early recognition of cecoappendicular pathology.

The appendix can be visualized either normal or abnormal in at least seventy-five per cent. of cases. The method of choice is the administration of the ingested barium meal. By means of the opaque enema, the percentage of visualization is extremely small. The majority of observers feel that it can be seen at the termination of the sixth hour, but in my own work I have been able to demonstrate it only rarely at this time because the large amount of barium in the ileum obscures its shadow. I have been more successful in bringing it to view in upwards of the ninth hour and generally at the twenty-fourth. It is of utmost importance that a combination of both radiography (at times stereoscopic) and fluoroscopy be utilized because if films alone are used, omitting screen search, the organ may not be revealed.

The mere position of the appendix without other signs is of negligible significance. Most commonly, it is situated along the internal or median border of the cecum and not infrequently hidden behind the terminal ileum and its mesentery. According to Kelly, forty per cent. of appendices are hidden behind the ileocecal junction. This author also describes the various directions in which an appendix may point as follows:

1. Lateral to the cecum
2. Behind the ileocecal junction
3. In the iliac fossa
4. Along the iliac vessels
5. Into the pelvis
6. To the promontory of the sacrum
7. Among the small intestines
8. Mesial to the cecum over the ileum
9. Mesial to the cecum under the ileum
10. Behind the cecum

Fluoroscopic observation at varying periods of time following the ninth hour after the opaque meal shows that the appendix is not in a constant position but moves from one to another area. If, therefore, we rely upon a pressure sensitive McBurney point as always indicating chronic appendicitis, we are in many instances misled because the appendix may be in an entirely different location. McBurney, in 1889, in his masterful presentation of the subject, states, "I believe that in every case the seat of greatest pain, determined by the pressure of one finger, has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus. This may appear to be an affectation of accuracy, but, so far as my experience goes, the observation is correct." Röntgenology has proved that the McBurney point is not necessarily the landmark of the appendix and I feel quite certain our surgeons will agree that it is many times necessary to hunt for it in regions quite remote from the McBurney point. A pressure tender McBurney point may be due to conditions other than chronic appendicitis.

The sensitive appendix, the tip of which points upward, is generally of the adherent type.

Is the fact that the appendix can be visualized by the entrance of an opaque substance in itself of any importance?

Various opinions are entertained. Some continental observers regard the capability of its demonstration as evidence of disease. Case says, "It is to be presumed that when the appendix rids itself promptly of the bismuth mixed cecal contents, the fact of the entry into the appendix is of little consequence, but when the cecal contents are retained for several days, perhaps even weeks, one may certainly conclude that under favorable circumstances, when the fecal mass is especially rich in pathogenic bacteria, its retention within the appendix will be a matter of greatest importance. Hence, when the appendix remains visible for more than a day or two following bismuth examination, it is in proportion to its poor drainage, a dangerous appendix."

---

*Read before Buffalo Academy of Medicine, May 3, 1922.

The results of our work have led me to place but slight stress upon defective drainage in itself. If we base the diagnosis of appendix pathology upon this occurrence alone, our surgical friends will not only disprove this statement but will become skeptical as to the real value of the röntgen method.

Motor insufficiency of the stomach is not uncommonly due to primary relaxation of the muscular walls brought on by overeating, too great a use of tobacco, irregular habits, the anemias, infectious diseases, gastroenteroptosis and chronic constipation. Why, then, is it not conceivable that prolonged retention in the appendix may be the result of similar etiological factors without there being any actual pathological changes in the appendix? When, however, hypomotility is accompanied by a pressure tender point elicited in the course of fluoroscopic or visible palpation, we have one of the most reliable signs indicating disease.

We have seen appendices after removal declared normal by surgeons, which retained barium for upwards of forty-eight hours, but were free of pressure tender points during the screen examination. In a word, prolonged retention minus sensitiveness we do not consider demands operative procedure and from subsequent histories in certain of the operated cases we find the various symptoms complained of have in no way been alleviated by the operation.

Ileac stasis is considered by some as constituting one of the röntgen signs of appendix disease. This is seen so often in individuals who have normal appendices and in many who have had their appendices removed that its occurrence does not carry great weight as a diagnostic point in this disease. In fact, most patients who are constipated show evidence of socalled ileac stasis due to back pressure from the cecum. Incompetency of the ileocecal valve occurs so commonly that we believe it only worthy of passing mention.

More important than ileac stasis or ileocecal incompetency is the phenomenon of pylorospasm, which may at times be induced by palpation of the appendix.

It is of the utmost importance to know that the vague stomach symptoms in appendicitis find their explanation in a socalled pylorospasm. We not only have clinical methods, but also x ray findings, which are called forth by a spasm of the pylorus.

In no way can we estimate the motor activity of the stomach so well as by an x ray examination, and the effect of pylorospasm can be read directly off the fluoroscent screen. Of course, this does not absolutely prove the presence of pylorospasm, but as near as can be judged, it enables us to assume its existence with the greatest degree of certainty.

In deciding whether the appendix is truly sensitive to pressure, the question of palpation is one of utmost importance and its technic must be carefully practised.

Most röntgenologists use the gloved hand or a wooden spoon called a distinctor. We have used both and discontinued them because the tactual sense is lost, supplementing them by using the lead-rubber glove from which the middle finger has been removed, thereby permitting the uncovered finger to be unencumbered and suitable for palpation.

In this manner direct pressure can be brought immediately over the appendix and its degree easily determined. With the gloved hand or distinctor it is not possible to palpate as gently as with the uncovered finger and tenderness may be induced by these protecting devices because much more pressure is brought into play than is realized. The degree of pressure with the one may elicit pain that is entirely lacking with the finger method. A large magnifying lens is often of great help in the fluoroscopic study.

It is true that by carrying out this technic the operator is negligent regarding his own protection, but the risk is no greater than that which the surgeon assumes who exposes himself to infection at the operating table or the clinician who comes in contact with various types of infectious diseases.

A visualized appendix that retains barium after the cecum has emptied, and is sensitive to visible palpation, is strong evidence of appendicitis. If drainage is defective for a number of days or weeks and a persistent pressure tender point exists, there can be no doubt as to the diagnosis.

The presence of adhesions can frequently be determined. If the appendix and cecum are freely movable, it is safe to assume that none are present. If the tip is adherent, it remains in a fixed position while the remainder can be made to move.

The entire appendix may be adherent in which case immobility is demonstrated unless it is bound securely throughout its entirety back of the cecum.

If the lumen is occluded, it is my belief that a pathological condition is present, since chronic inflammatory changes in themselves produce obliteration. Inflammatory exudate, constriction, concretions at the proximal end, or adhesions causing sharp angulation, prevent the entrance of the barium mixture.

If curling or kinking is seen, the examination should be repeated, always bearing in mind the liability of the appendix to change its shape. But, if the deformity is persistent, its production is likely due to pathology.

If the appendix appears to be constricted in one or more segments, reexamination is again indicated to prove the permanency of such defects and to rule out the possibility of the deformity being the result of peristalsis or spasm.

In comparing the degree of involvement in a large number of cases, in which the lumen was patent, with those of the nonpatulous type, I have found in following them to operation that more extensive pathological changes exist in the obliterative or nonpatulous type.

CONCLUSIONS.

Many symptoms are common to numerous abdominal conditions. The x ray is of value in their differential diagnosis, and most always is capable of eliminating certain organs and detecting the offender.

Obscure symptomatology may be due to unsuspected appendix disease discovered in the course of an examination of the gastrointestinal tract.

Tenderness over the McBurney point does not necessarily indicate appendicitis, because the appendix may be remote from this site. Its location can be determined by the fluoroscope.

An appendix that retains barium after the cecum has emptied is not necessarily diseased.

Size and position in the absence of certain signs are of scarcely any significance.

Leftsided appendix can be demonstrated by no other method.

Reiterating the röntgen evidence of appendix involvement we have:

1. A visualized appendix that is definitely sensitive to fluoroscopic palpation.
2. Inability to visualize the organ because of obliteration of its lumen together with the pressure tender cecum.
3. Persistent kinking or constrictions.
4. Concretions.
5. Adhesions.
6. Reflex pylorospasm.

Tuberculosis Within the Rectum

By CHARLES V. DRUECK, M.D.,
Chicago.

Tuberculosis within the bowel occurs rarely in the miliary form, but presents itself more commonly as ulcerative and occasionally as hypertrophic changes.

Miliary tuberculosis of the rectum usually is secondary to tuberculosis of the genital organs, more particularly the prostate, and begins with deposits which feel like bird shot beneath the mucous membrane. The mucosa is pale and anemic, except that immediately about the nodule where there is a ring of congestion. This stage may continue for a long time, but at any moment the little nodules may become yellow, caseate and break down into little, cuplike ulcers, which later coalesce to form large ulcers, or several small ulcers may be connected by burrowing underneath the mucous membrane.

Ulcerative tuberculosis is the more common expression of this disease in the bowel and is usually secondary to pulmonary tuberculosis. Infection begins in the solitary follicles and in Peyer's patches, but later spreads into large, irregularly shaped ulcers which follow the course of the bloodvessels. Thus, in the rectum these ulcers spread in all directions, while in the sigmoid they have a tendency to encircle the bowel.

The whole mucosa of the bowel is pale and anemic, except closely around the tubercle, where a ring of congestion appears. Later the tubercle gradually fades to a yellow color as caseation advances and finally breaks down into an ulcer with a ragged wormeaten base, surrounded by an infiltrated and indurated base which is sometimes undermined. In the necrotic base of the ulcer are seen little, yellow tubercles. These ulcers may extend all around the bowel and have little sinuses running beneath the mucosa from one ulcer to another. If the ulcers are close together the intervening bridge of tissue may slough away and thus a large irregular ulcer appears, perhaps extending entirely around the bowel. (Fig. 1.)

This necrosis may be confined to the mucosa and submucosa or it may extend to the muscular and serous coats but it rarely causes perforation. During this sloughing of tissue the various other bacteria of the colon add to the systemic poisoning. Beneath the ulceration is a deposit of fibrous connective tissue.

SYMPTOMS.

The local symptoms of tuberculous ulceration of the sigmoid or rectum are lumbar or sacral ache and rectal tenesmus, accompanied with diarrheal evacuations of pus, blood and mucus. The earliest symptoms of the coloproctitis, and showing the disturbed digestion in general, is the voiding of gas and mucus and an associated irregular colicky pain and abdominal distention. As soon as the tubercles break down, and erosion begins, blood is mixed with the mucus and discharges and severe hemorrhages sometimes occur when the ulceration erodes a blood vessel. If the bleeding is oozing in character it may be persistent and considerable blood be accumulated and retained within the rectum. The stools are diarrheal, dark in color from the added blood, and foul, gangrenous in odor. Sometimes the stools are partly formed and tarlike from the mixed blood.

Tenderness may not be present unless the peritoneum above or the sphincter region below is involved.

Stenosis and even obstruction may occur although death intervenes usually on account of failure of nutrition. The diarrhea is slight at first, but increases as the ulceration spreads, until thirty or forty evacuations occur daily. Bleeding is not profuse, but as the oozing is persistent the blood may accumulate and be retained in the rectum, and when voided may be fresh, or tarlike, or mixed with feces.

DIAGNOSIS.

Tuberculous ulceration of the bowel should be looked for in every patient when diarrhea occurs that cannot be accounted for by overeating or improper food, or by any other dietetic errors, and which does not promptly yield to treatment. A careful proctoscopic examination may fail to find the ulcers but when present in the sigmoid or rectum they are typical and easily recognized. Tubercle bacilli in scrapings from the ulcer are strong evidence of the nature of the trouble, although the possibility of accidental deposit of the bacilli on a nontuberculous ulcer must be remembered. The clinical picture is, however, somewhat characteristic: 1. The presence of tuberculosis elsewhere, as in the lungs, lymphatics, or the genitourinary system; 2, ulcers which follow the course of the bloodvessels and in the rectum spread out irregularly in every direction; 3, diarrhea, discharge of mucus, blood and pus with rectal tenesmus; 4, general emaciation of the patient with great loss of body fat. This may be expressed by the consumption of the perirectal fat and a shrunken or funnel shaped anus.

DIFFERENTIAL DIAGNOSIS.

The differentiation of a tuberculous ulcer from that due to some other irritation is essential. Theoretically this should be easy, but practically it is much more difficult, because often the classical symptoms are lacking or confused. It is probable that tuberculous ulceration of the terminal bowel (sigmoid and rectum) is much less frequent than is generally supposed. When patients with rectal ulceration become emaciated the conclusion frequently is that the process is tuberculous. Any ulceration in the lower colon produces dysentery which contributes to imperfect nutrition and the clinical picture of tuberculosis, but the character of the ulceration differs with each causative factor. Rectal ulcers of any type are intractable, and are therefore often believed to be tuberculous. Amebic ulcers may be mistaken for tuberculous lesions, but the amebic sufferer passes through many periods of symptomatic cure followed by sharp relapses, quite in contrast to the story of tuberculosis, which grows progressively worse. In amebic ulceration there is little variation of temperature and the pulse rate is increased only as exhaustion becomes pronounced. In tuberculous ulceration elevation of temperature and acceleration of the pulse rate are always present.

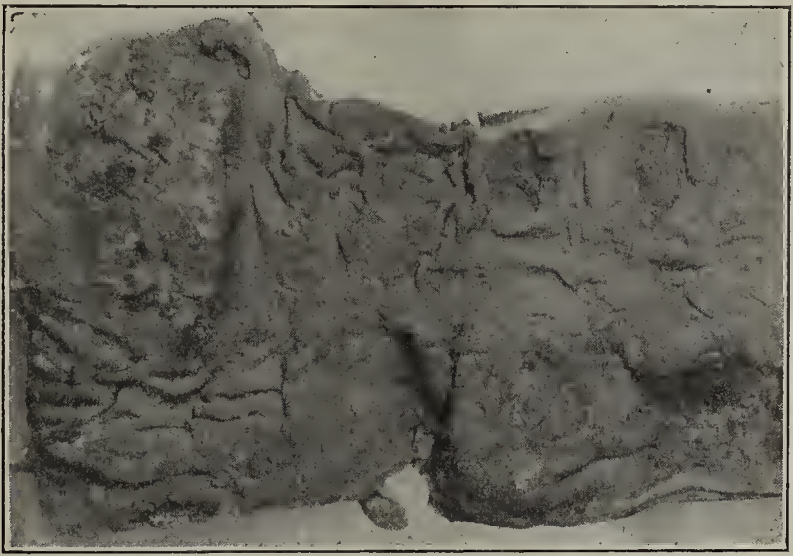

Fig. 1. Tuberculous ulcer of the sigmoid.

Cancer by the time it reaches the ulcerative stage fills the lumen of the gut and causes obstructive symptoms.

A syphilitic ulcer has a punched out appearance with raised edges, while the tuberculous ulcer is irregular in outline and has an uneven base (a worm-eaten appearance).

TREATMENT.

What has been said of the prophylactic treatment of tuberculosis at the anus will apply similarly here.

The same principles govern the active treatment of tuberculosis of the pelvic colon as apply to tuberculosis elsewhere in the body, that is, living in the open air as much as possible, particularly at night, little physical work or mental strain, and a highly nutritious diet.

Internal medication has very little influence except for relief of specific symptoms. Salicylate of bismuth is often required for the diarrhea. When the ulcers can be found with the proctoscope, they should be cocainized and then cauterized with pure crystals of permanganate of potassium.

HYPERPLASTIC TUBERCULOSIS.

This type of tuberculosis is characterized by the formation of a dense hypertrophy instead of caseation and necrosis, and may be confused with syphilis or scirrhous cancer of the bowel. The existence of tuberculosis elsewhere in the patient should put the physician on his guard.

SYMPTOMS.

A proliferating stenosis, with great thickening of the wall of the bowel and including the peritoneum, develops, instead of the ulcerating cavities found in the ulcerative tuberculosis of the bowel. These lesions are found in the cecum and appendix, as well as in the sigmoid and rectum. The patient has the same diarrhea, tenesmus, sacral pain and rapid loss of weight as in the ulcerative type of tuberculosis, although as the stenosis develops there is a gradually increasing constipation with the passage of mucus and later also pus and blood.

This hyperplastic form of tuberculosis is frequently mistaken for cancer or diverticulitis, and is only differentiated by microscopical examination. Lartigan (1) states that it is purely a local tuberculosis as the lungs and other organs are rarely involved. Lynch has also found this type of tuberculosis as a primary lesion in the sigmoid and rectum.

Treatment of hyperplastic tuberculosis consists in the surgical removal of the diseased area using the cautery instead of the knife, and following this with the usual upbuilding course as in any form of tuberculosis. The use of tuberculins is gaining in favor but the proper method of administering them is most important so as not to produce a negative phase.

Because rectal tuberculosis is secondary to this same infection elsewhere it is usually the lesser complaint, and the patient succumbs to the primary trouble before stricture of the bowel becomes severe; but in some instances obstructive symptoms are present. If stricture occurs, a removal of the diseased part of the bowel by resection is the only treatment.

Gastric Ulcer and Suprarenal Hypofunction.—E. Martinez (*Aragón Médico,* January, 1922) concludes that in those having adrenal insufficiency there is manifested a vagotonicity, probably due to hypoadrenalinemia; that there exists at the same time a predominant activity of the lymphatic system with proliferation on the part of the lymphatic ganglia of an intensely vagotonic character; that resistance to infection is low; that the marked vagotonicity creates a condition favorable to development of gastric ulcers.

A New Type of Drain for Use in Anorectal Fistulæ

By J. F. MONTAGUE, M.D.,
New York,
Rectal Clinic at University and Bellevue Hospital Medical College, Fellow of the American Proctologic Society.

In the postoperative treatment of fistulæ lies the secret of their cure. For regardless of how painstaking a surgeon may be at the time of operation, if he is not efficient in the guidance of the healing process troublesome pus pockets, bridges of tissue, and innumerable complications are likely to occur.

It has been customary to treat fistulæ after operation by packing with gauze strips. Thus, by keeping the edges of the operative wound apart, granulation of the bottom of the wound is induced and allowed to progress until the area is entirely filled in. In this manner the healing occurs from the bottom up and the dangers of recanalization, bridging, and so forth are avoided. While the theory of this is ideal its practice often appears rather difficult. The reason that I have ascribed for this is that the material used for the pack, or drain as I prefer to call it, has certain deficiencies.

The proper dressing of a fistula wound of any considerable size with the ordinary gauze drain requires an appreciable amount of skill. The gauze drains are, of course, light and frail and, moreover, when packed in tubes, acquire a certain springiness and tendency to curl. All of these qualities render their manipulation more or less difficult. I do not believe gauze drains are very efficient for conveying medication nor do they stay in position particularly well. Then, too, when granulations begin to form they frequently grow into the mesh of the gauze and when this is removed the granulating tissue may be damaged and bleed profusely.

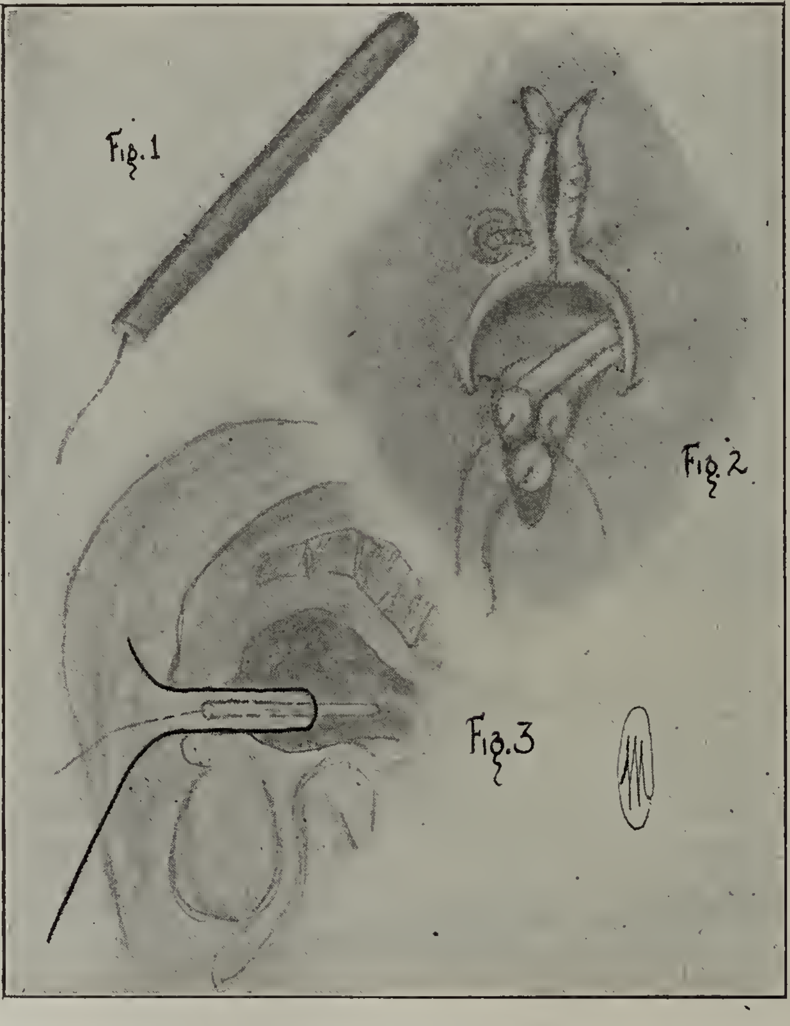

FIG. 1. Roll of absorbent cotton, quarter of an inch in diameter, to be used in author's drain for anoretcal fistulæ.
FIG. 2. Application of the fistulæ drain.
FIG. 3. Insertion of drain through a small sized endoscope.

In an endeavor to find a material or device which would obviate the shortcomings of the gauze drains just described, I contrived the following fistula drain which has given very great satisfaction in the University and Bellevue Hospital Medical College Rectal Clinic, at the Lexington Hospital, and in the hands of several other surgeons in this city to whom I suggested such drains for trial.

They consist, essentially, in a roll of absorbent (Fig. 1) cotton quarter of an inch in diameter and either four, six, or eight inches in length. Through the centre of this roll is run a piece of stout tape which extends beyond the roll for about three inches. The object of the latter is to serve for traction when it is desired to remove the drain, the cotton itself becoming very friable when wet. These rolls may be saturated with whatever medication it is considered desirous of applying to the fistulous wound, such as balsam of peru, Dakin's solution, argyrol and so forth. More medication may be conveyed in this manner than with the gauze drains and in addition the cotton rolls give up the medicaments more readily. Should one drain be insufficient to keep the walls of the wound apart two or three may be used. The roll drains are small enough in diameter to allow three or more to be placed in a wound without causing so much pressure that granulation is impeded or reunion of the sphincteric fibres prevented.

APPLICATION OF DRAINS.

The application of the drains I have suggested is very easy and may be done with either a bivalve speculum, such as a Bodenhamer, with the aid of a pair of anatomical forceps and a blunt rod (Fig. 2), or else a drain may be inserted through a small sized endoscope, the latter being withdrawn leaving the drain in the anal canal (Fig. 3). By gentle traction and guidance with a blunt rod the drain is placed into the fistulous wound.

The advantages of this type of drain are many and once they are used the old type of gauze drain becomes obsolete in fistula cases. They are easily placed and retain their position very well. Moreover, they are easily withdrawn by a little gentle traction on the tape. They do not adhere to the granulation tissue, nor do they leave cotton fibres in the wound as gauze occasionally does. They drain much better than gauze does and also, owing to their shape, act far more efficiently than gauze does in keeping the wound walls apart. Infection never occurs in a wound where pocketing and bridging are prevented. This to my mind renders them much to be preferred to gauze drains which occasionally permit tissue bridges to form. Finally, the fistula drain I have devised may be easily sterilized and kept so in sterile jars. Each one is handled individually, which makes the possibility of contamination less than in gauze strips that are cut off anther piece. Although attempts at sterility may seem futile when one works in the region of the rectum, I firmly believe that aseptic surgery, in so far as is possible, is just as much in order here as elsewhere.

An Instrumental Aid to Sigmoidoscopy

By DESCUM C. McKENNEY, M.D., F.A.C.S.,
Buffalo, N. Y.

The value of the sigmoidoscope for the inspection of the lower twelve inches or more of the colon is conceded; and, knowing the frequency of disease in this portion of the bowel, no routine examination of a patient is complete unless such an examination is made. In this way the cause of the patient's trouble is often determined by finding an unsuspected cancer, ulcer, polyp or stricture. No surgeon has any right to operate on a lower rectal or anal condition until he has convinced himself that the bowel is free from pathological conditions higher up.

There are many kinds of sigmoidoscopes. Each has an obturator, which makes possible its easy insertion through the anal canal into the lower rectum, at which point the obturator is removed and the instrument is then passed onward, under the guidance of the eye, with the aid of direct or reflected light. The pneumatic sigmoidoscope is designed to keep the bowel in advance of the distal end of the instrument, out of the way by inflating it with air. This, in some cases and often where most needed, does not work, as lack of tone of the external sphincter ani muscle permits the air to escape around the instrument so that distention is not possible. Other operators pass the sigmoidoscope as far as possible, withdraw the obturator, and with the eye observe what they believe to be a continuation of the lumen, into which, after replacing the obturator, they endeavor to advance the instrument, proceeding in this manner until they have accomplished their purpose. Sometimes, after the sigmoidoscope has been passed into the rectum, it can be advanced, if done gently, without the obturator and without injuring the mucous membrane, providing the edge of the distal end of the instrument is blunt.

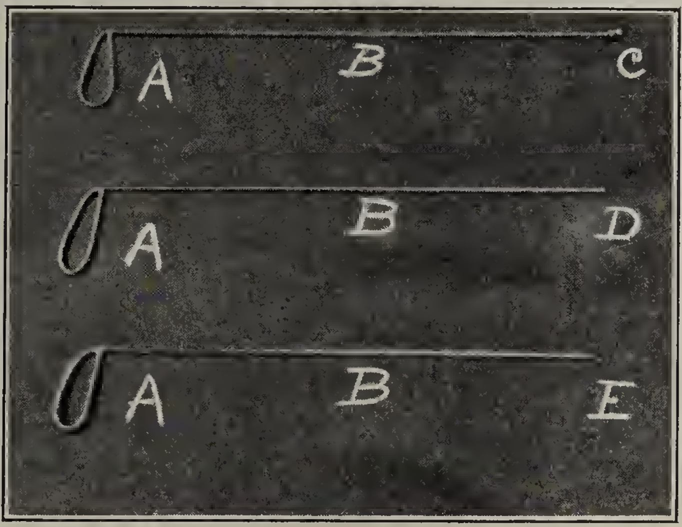

Fig. 1. Parts: a pistol grip, b shaft, c acorn tip. The pistol grip and shaft are made from one piece of brass rod, 5/32 inch in diameter, and the acorn tip is ⅜ inch in diameter with the large end of the acorn distal. When one uses a sigmoidoscope with a small lumen the acorn tip will to some extent obstruct the view, so the instrument may be made without this tip but with the end of the rod, which should be 3/16 inch in diameter, rounded bluntly, D. It is often advantageous to have ⅜ inch of the tip bent at an angle of 155° with the shaft E.

No matter what sigmoidoscope or method of passing it is used occasionally unusual difficulties present themselves. It is with the idea of surmounting these difficulties, as far as possible, that the instrument about to be described has been devised.

USE OF THE INSTRUMENT.

The knee chest and Hanes's positions are the best for sigmoidoscopy. With the distal end of the sigmoidoscope, preferably one with a bluntedged end, inserted into the rectum, the obturator is withdrawn and the described instrument, which may well be called a pathfinder, takes its place. Perfect vision is assured by means of two features in the pathfinder, one being the pistol grip which permits the hand manipulating the instrument to operate at one side of the proximal opening of the sigmoidoscope, and the other being the small size of the shaft which occupies practically no room inside the tube. When the operator sees what he believes to be the lumen he passes the acorn tip into it, if it will go; if not, by withdrawing slightly or otherwise shifting the end of the sigmoidoscope another suspected continuation of the lumen is brought into view, and, if the tip passes into it, it is advanced as far as it will go without using any force. Then the sigmoidoscope, now that the way has been found, is slipped over the pathfinder to its end. The same maneuvre is repeated as frequently as necessary to complete the examination.

Helpful in the passage of the instrument is to have the patient breathe deeply. Gentle manipulation of the abdominal wall during the examination often dislodges the pelvis colon from the pelvis and straightens it so the instrument can be more easily advanced. Gentleness to avoid spasm is always essential.

Inasmuch as one can always see what he is doing there is no danger of puncturing the bowel with this instrument.

In addition, by using this instrument as the finger is used for palpation, one is able, among other things, to estimate the amount of bowel spasm, the size of the pedicle of a polyp, the amount of induration about a growth or ulceration and whether or not there are adhesions.

Duodenal Intestinal Obstruction, Secondary to Gastric Polyp and Intussusception Due to Multiple Teniæ Saginatæ*

By JOHN W. SHUMAN, M.D., F.A.C.P.,
and DOUGLAS CRUIKSHANK, B.A., M.D., C.M.,
Beirut, Syria.

Comment concerning the failure of the colon to rotate during embryonic life needs only passing mention in this instance because it is not a rare happening.

The fact that five distinct heads of bovine tapeworms were found, at autopsy, anchored in the mucosa of the first portion of the ileum, demonstrates clearly that textbooks are somewhat misleading in that they leave the reader with the opinion that one and only one tapeworm inhabits the intestinal tract of man at a time. Statements by Dr. Adams, the former, and Dr. Webster, the present, director of anatomy here are definite in stating that they have frequently found multiple teniæ saginatæ in cadavers. However, this is the converse of the solitary worm of pork tenia solium.

The intestinal obstruction is worthy of record because its cause, location and action were unique. The lethal result was inevitable for, when admitted to the hospital, the patient was moribund.

The cause was a new growth springing from the stomach wall just inside the pylorus, which acted like a plug in the first portion of the duodenum causing a spasm about it, and permitting it with the surrounding gut to slip into the next portion of the intestine, an intussusception, with hypertrophy of the gut below. An abbreviated history and autopsy report follows:

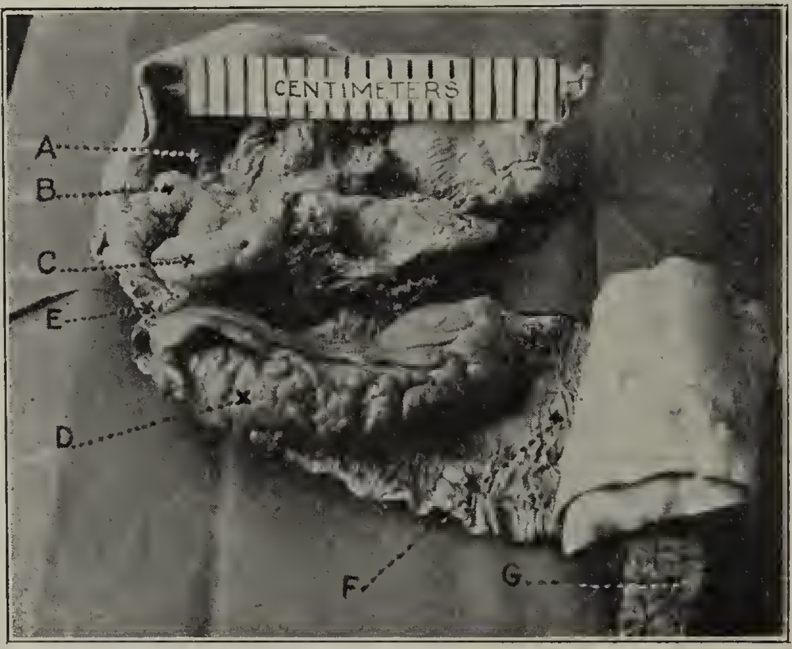

Fig. 1.—A. Normal rugæ. B. Hypertrophied rugæ. C. Smaller polyp. D. Larger polyp. E. Pylorus (unopened). F. Hypertrophied and dilated duodenum and jejunum. G. Normal small intestine.

Case I.—No. 17591. Female, aged thirty-five, was referred by Dr. H. G. Dorman to the medical service of the American University Hospital at 6 p. m. November 14, 1922, complaining of "vomiting one half hour after taking anything into the stomach, which began five weeks before, after lifting a heavy object and drinking copiously of water. A doctor was called who prescribed an anthelmintic, which resulted in the passing of a worm. Getting steadily weaker on account of not being able to retain food and bowels moving scantily every two or three days."

Physical examination evidenced a markedly emaciated and prostrated woman. Her abdomen was moderately distended. Peristalsis was visible from left to right. Tympanitis was elicited from the xyphoid to three fingers' breadth below the umbilicus. The lower border of this tympany had its convexity downward (stomach?). A long, round, hard mass felt in the right abdomen extending from the iliac fossa up to and under the costal margin. This was thought to be the cecum impacted with feces.

Prognosis notes under date of November 15th stated that repeated enemas (seven) were given, all but two attended with only fair results—hard, fecal masses, segments of teniæ and some dark blood. Death occurred on November 16th at 9 a. m. and autopsy followed at 9:30 a. m. the same date.

An abdominal incision opening into the stomach was made (which appeared to fill the whole upper abdomen) and liberated from one to three litres of clear, colorless fluid. A large sausageshaped mass, that was apparently small intestine, lay along the right side of the abdominal cavity. The cecum with the appendix in front of it, lay in the left iliac fossa. The appendix was white and firm and the proximal end distended to the size of a lima bean with hard masses that grated together like stones on being handled.

The colon contained a small amount of thick red fluid suggesting altered blood. The ileum was of normal size and contained a greater amount of this red fluid and in addition larger masses of live tapeworm, from among which five heads were isolated (teniæ saginatæ). The jejunum was greatly hypertrophied and within its proximal lumen there was a gangrenous mass of tissue. This and the duodenum formed the sausageshaped mass referred to above. The duodenum was opened and this mass traced upwards. It was a greatly congested, lobulated polyp ten inches in length and two and one half inches in diameter attached within the stomach to the anterior surface just proximal to the pylorus (Fig. 1). Another polyp about three inches in length extended from beside the larger one into the duodenum. The smaller polyp was greatly congested but not gangrenous. The rugæ of the stomach were marked and one was especially hypertrophied and apparently in process of becoming larger like the polypi just described. These polypi were apparently formed entirely from the mucous lining of the stomach and did not seem in any way to have thickened or infiltrated the submucous layers of the stomach wall. The stomach was enormously dilated. The pyloric end had become invaginated into the duodenum to form an intussusception three inches in length. The peritoneal coverings of this area had become firmly adherent where in contact. The opening of the bile duct was patent within this area of intussusception. Gangrene had occurred only on distal end of largest polyp. Microscopic section from middle of largest polyp showed it densely infiltrated with small round cells. Bloodvessels were numerous and congested with red cells. Superficially there was ulceration. There was moderate hyperplasia of racemose cuboidal epithelium, confined to a definite superficial layer of the tumor and not infiltrating the deeper parts. The glandular cells were regularly arranged on a basement membrane with deeply staining nuclei at the base. Many of the acini were filled with desquamated degenerating cells. There was no suggestion of malignancy in the epithelial tissue.

---

*Read at the fortnightly meeting of the American University of Beirut Pathological Society. November 20, 1922.

The underlying tissue, which constituted the great bulk of the tumor, was hyperplastic connective tissue consisting of irregularly arranged masses of oval, spindle shaped and oat shaped cells lying in the matrix which had the character of a fine network of edematous fibrin. The nuclei of the cells stained faintly and the cytoplasm was granular. Few mitotic figures were seen. Embryonic connective tissue, nonmalignant, was present.

CONCLUSIONS.

1. That the cause of death was starvation secondary to duodenal obstruction from a nonmalignant polypoid growth.
2. That early operative interference might have averted death.

Thrombosis of the Superior Mesenteric Vessels and Volvulus of the Small Intestine. Resection and Recovery*

By DAVID H. ORGEL, M.D.,
New York.

The infrequent occurrence of this condition and the small number of cases reported add interest to the case reported herewith. Whether the thrombosis of the mesenteric vessels was primarily and the volvulus secondary, or vice versa, cannot be determined. In an exhaustive résumé of the entire subject Klein (1) admits that either condition may be primary or secondary.

CASE.—A. U., male, aged nineteen, was admitted to the City Hospital on January 11, 1923, at 10 a. m. His previous history was negative; his bowels were regular and he had no pains in the abdomen. His present illness began on January 10, 1923, the day before admission to the hospital. After dinner, at noon, he had gone for a walk and was suddenly seized with pain in the abdomen. He took a dose of castor oil, but this did not relieve the pain and he commenced to vomit. Pain and vomiting increased and at 6 p. m. he called a doctor who prescribed some medicine which did not relieve either pain or vomiting. Three enemas were given with no result, except for the return of clear water. No blood was passed per rectum. The doctor was called again at midnight and gave him a hypodermic of morphine. He was unable to sleep, however, the pain and vomiting continued, and he was removed to the hospital in the morning.

Physical examination on admission showed the patient in a state of shock. He looked weak, his pulse was 160, respirations were rapid, temperature was 99.2° F., and he was in great pain. Physical examination was negative except for the abdomen. There was marked generalized rigidity of the whole abdominal wall with tenderness throughout, increased in right iliac fossa. The abdomen was protuberant and distended. The diagnosis on admission was acute appendicitis with general peritonitis.

On opening the abdomen through the right rectus incision a large amount of bloody fluid escaped. Several coils of the small intestine from about six inches above the ileocecal valve were deep chocolate brown in color, twisted upon themselves, and some coils were twisted through a rent in the mesentery which was dark in color and friable. The mesenteric vessels were thrombosed and did not bleed when cut across. The gut was thickened and indurated and showed a sharp line of demarcation at either end from the healthy intestine. Seven and a half feet of small intestine were removed (without untwisting coils) and an end to end anastomosis made with the Murphy button (on account of the necessity for rapid work) reinforced with two rows of Lembert sutures. The thrombosed vessels were ligated, mesentery was tied off distal to the thrombosed area, stumps of vessels covered with perotineum and ends of mesentery approximated. The abdomen was washed out with normal saline solution and, filled with it, then closed by layer sutures without drainage.

The patient had a stormy time for a few days. Gas was passed by rectum on the second day; bowels moved normally on January 16th, fifth day; the Murphy button was passed by rectum on the seventh day; stitch abscess of the abdominal wall developed on January 21st, which healed. He was discharged on February 4, 1923, cured.

The chief interest of this report lies in the large amount of intestine affected by the thrombosis, its resection, and the recovery of the patient. This was due in a large measure to the early recognition of the acute abdominal condition, the patient's removal to the hospital, and immediate operation. I believe from the operative findings, that is, occlusion of the bloodvessels and the condition of the mesentery, that thrombosis of the mesentery vessels was the primary cause of the condition. The etiological factor I was unable to determine.

THE BLOOD IN GASTROINTESTINAL MORBID PROCESSES

With the exception of the esophagus, the rectum, and a portion of the sigmoid, it is still often impossible to affirm the development of a lesion of the gastrointestinal tract; hence the means offered by the laboratory for diagnostic purposes should be resorted to, and among these, hematology.

From a general viewpoint, a decrease of the red cells and a lowering of the percentage of hemaglobin are constant in chronic infections and hemorrhagiparous affections and cancer. The anemia will be all the more marked, the more serious the morbid process. Leucocytosis is a vulgar datum, nevertheless it may be said that the degree of leucocytic reaction depends upon the nature of the infection, its gravity and development, the patient's resistance, the complications, and all morbid associations.

Polynuclear leucocytosis is a normal reaction in acute affections; a sudden rise of leucocytosis above thirty thousand is an important presumptive sign in favor of an acute peritoneal reaction. In chronic affections a polynuclear leucocytosis may indicate a lesion of the stomach, duodenum, gallbladder, or large intestine, sufficiently profound to reach the peritoneum and to provoke a plastic reaction of the serous membrane in the region of the lesion.

A mononuclear leucocytosis is met with in about fifty per cent. of the cases of cancer of the digestive tract at its onset, and it is constant in chronic appendicitis. The large mononuclears predominate in gastric and duodenal ulcer, gastric cancer and chronic appendicitis. Medium sized mononuclears and lymphocytes predominate in fifty per cent. of the cases of gastric cancer, syphilis of the liver, and in forty per cent. of the cases of appendicitis. Eosinophilia accompanies parasitic invasion, rectal cancer and serious forms of colitis, which may also be of parasitic origin.

From the local viewpoint, when a gastric lesion exists, the anemia is quite as marked in a bleeding ulcer as in cancer. It is not marked in gastric syphilis. Leucocytosis is *nil* in ulcers, more marked in syphilis, and still more so in cancer, where the polynucleosis attains a high degree in fifty per cent. of the cases, mononucleosis in thirty per cent. and a normal count in twenty per cent. There is a moderate mononucleosis in gastric syphilis, the large mononuclears predominating. Duodenal ulcer offers the same hematological changes as gastric ulcer.

Anemia is very marked in the diarrhea of tuberculous enteritis, while if a diarrhea is due to intestinal parasites or a latent amebiasis, eosinophilia is present. The count is normal in nervous diarrhea. All infections of the liver and biliary tract give rise to distinct polynuclear reactions, while a marked eosinophilia is present in cysts and amebic abscess of the liver. Colonic cancer invariably causes a polynuclear leucocytosis, while in rectal cancer the blood changes are the same as in gastric malignant processes.

AZOTEMIA AND GASTRIC ULCER

The recent work of LeNoir and his coworkers has drawn particular attention to the secondary reaction of gastric affections on the kidney. Rendu, although not maintaining that uremia depended upon a gastric lesion, drew attention some time ago to the possible superposition of these two processes, which have no common pathological bond, and from this fact he demonstrated the difficulty of making a differential diagnosis between cancer of the stomach and gastric uremia, since both affections could be encountered in the same patient. Treitz has reported similar cases of gastric ulcer and uremia, Barié uremia and duodenal ulcer, Lancereaux uremia and ulcer of the large intestine.

This morbid combination is, however, an infrequent pathological phenomenon and should lead the practitioner to search for the organic gastric lesion and what Le Noir, Richet and Jacquelin have demonstrated conclusively is that it is not merely the superposition of the two processes but the dependence of the renal lesions on the gastric lesions. Because their researches have not only been of a pathological nature, but above all clinical and biological, it may be more exact to say that there is dependence of the functional renal disturbances on the gastric ulcer, this being the inverse of most cases in which gastric disturbances depend upon renal lesions and the uremia resulting therefrom.

Let it be understood that the condition under consideration is in no way related to dyspeptic albuminuria. Clinically, the nephritis due to gastric ulcer rarely gives rise to albuminuria and edema and there is no high blood pressure; it manifests itself especially by a mild azotemia amounting to fifty or sixty centigrams and an increased Ambard coefficient. In a word, the nephritis develops silently during the progress of the ulcer and will be detected only by biological reactions.

In thirty-eight cases of gastric ulcer in which azotemia was searched for, Le Noir and his coworkers obtained the following interesting results: In fifteen cases with azotemia, this amounted to fifty to sixty centigrams; in six cases from sixty centigrams to one gram in five; from one to two grams in three and over two grams in one case. Ambard's coefficient gave concording results.

Gastric ulcer cases, therefore, frequently present azotemia. This appears to be more common in ulcers of long standing than in those of recent date, and nevertheless elderly patients seem to be more predisposed to it than younger subjects, and, what is more, the azotemia appears to be progressive in type.

These are not mere speculative statements; they admit of useful prognostic and therapeutical indications because these renal lesions, which are generally associated with hepatic lesions and are usually latent, manifesting themselves by humoral changes, nevertheless constitute a relative contraindication to operative procedures necessitating a general anesthesia.

SHOULDER PAIN IN THE DIAGNOSIS OF ACUTE ABDOMINAL PROCESSES

The recent studies of Mr. Z. Cope, of St. Mary's Hospital, London, are of considerable clinical interest. Phrenic shoulder pain varies considerably both in intensity and quality, it most commonly resembling an ache, and is regarded by the patient—and not infrequently by the physician—as a rheumatic pain. Sometimes it is very sharp and stabbing, or it may feel as if a nail were being driven in at the painful spot. Frequently the discomfort occasioned may not be sufficiently severe for the patient to complain of it, hence it is necessary to inquire about the pain in every case if one is to avoid overlooking the symptom. Some patients say they have no pain, but that there is a sensation of stiffness in the affected part. This pain is of diagnostic value in a number of acute abdominal processes.

Perhaps hepatic abscess gives rise to this symptom more often than any other abdominal affection and both Waring and Cope have reached the conclusion that shoulder pain accompanying abscess of the liver is seldom or never experienced unless the pus is threatening to perforate the diaphragm. Hence, in any case presenting symptoms of hepatic abscess, accompanied by shoulder pain, the abscess must be close to and irritating the diaphragm. It should be likewise stated that this pain may be the only symptom calling attention to such an abscess.

Phrenic shoulder pain is an important symptom in perforated gastric and duodenal ulcer. Though not invariably present, it is sufficiently constant for inquiry in every acute abdominal case. Sometimes the referred pain arises simultaneously with the abdominal, but occasionally it is delayed in onset.

With the perforation of a duodenal or pyloric ulcer the pain is usually felt in the right supraspinous fossa or over the right acromion process, less commonly just above the right clavicle. With an anterior perforation of the stomach the pain is more likely to be referred to the region of the left clavicle or left acromion process. If the perforation is near the cardia, and the escaping contents irritate the median portion of the diaphragm, pain may be felt over both acromioclavicular regions, while a sense of weakness in the upper arm in addition to the shoulder pain may be complained of, this perhaps being due to a reflex action occurring in the sensory fibres of some of the arm muscles.

It is, perhaps, not generally known that phrenic shoulder pain is present at some time or other in the evolution of nearly every subphrenic abscess, but generally is complained of only in the stage of active formation of the abscess. When once the abscess has become localized, probably no complaint of the shoulder pain will be made. The position of the referred pain varies according to the position of the pus collection.

Any inflammatory condition spreading from the gallbladder may cause phrenic shoulder pain. Acute cholecystitis does not cause it until the inflammation has extended beyond the confines of the viscus. The passing of a stone down the biliary ducts is not accompanied by this referred pain unless there is inflammation around the ducts. Rupture of an infected gallbladder may cause the significant pain. In gallbladder processes the pain is generally referred to the right supraspinous fossa, occasionally to the acromiodeltoid region.

Slow enlargements of the spleen do not lead to diaphragmatic irritation and its characteristic pain, but the local peritonitis consequent to a splenic infarct, and the irritation caused by collecting blood clots, are sufficient to produce the symptom.

On *a priori* grounds, Cope had supposed that acute pancreatitis should, by irritation of the left crus of the diaphragm, lead to phrenic shoulder pain and in one instance of this affection the patient emphatically stated that at the onset of the agonizing abdominal pain there was also pain in the left supraspinous fossa, which was relieved when the abdominal pain was relieved.

It is seldom that phrenic shoulder pain is a symptom in appendicitis, because it is infrequent for the infection to extend up to the diaphragm. With a long ascending appendix, however, or in cases where the cecum and appendix are much higher than normal, the symptom is to be expected, but it is rarely found in practice.

Clinical evidence supports the view that the position of the referred pain on the top of the shoulder varies according to the part of the diaphragm irritated. This conclusion is at variance with that reached by Capps as the result of his experimental irritation of the diaphragm in cases of pleural effusion. It is possible that the different results may be due to the difference between a mechanical stimulus and that due to inflammatory conditions.

All observers agree that irritation of the right side of the diaphragm causes pain on the right shoulder while left shoulder pain arises from some affection of the left portion of the diaphragm. The localization may be summarized as follows: Irritation of the anterior part of the diaphragm causes pain in the corresponding clavicular or supraclavicular regions; irritation of the posterior portion of the diaphragm causes pain in the supraspinous fossa of the same side: irritation of the top of the phrenic dome causes pain in the corresponding acromioclavicular regions, and finally, pain felt over both shoulders indicates a median diaphragmatic irritation.

THE HUNT FOR SPIROCHETES

The American literature upon general paresis receives an interesting contribution through Dunlap's report on localization of the spirochete. (Charles B. Dunlap: Recent Studies on Spirochetes in General Paralysis. *Archives of Neurology and Psychiatry,* December, 1922). He reviews the latest findings in this phase of the subject from European investigators, especially in Germany, estimating these also from his own researches. He mentions the new staining method of Jahnel which has enabled the latter to define the spirochete sharply leaving the nervous elements unstained. This has given opportunity for a more systematic hunt for the organism in its distribution and method of activity in the nervous tissue.

Spirochetes are most readily found in the frontal lobes, the seat also of their greatest ravages. Here it is chiefly in the middle and deeper layers of the gray matter where they are to be found, seldom in the pia or in the outer cortical layer, almost never in the white matter. They seem to lie along the fissures and at the tops of the convolutions. They appear in three types of distribution most frequently in wide diffusion but in small numbers. Yet they are sometimes grouped in foci containing even a perfect swarm of the organisms but showing no special relation to any particular nervous elements. At other times these foci have concentrated themselves around the vascular walls even penetrating them. They have practically never been demonstrated in the blood or cerebrospinal fluid of a human being in life although in this vascular focal form rarely a spirochete is found in the lumen of the vessel. It is believed that these focal colonies gravitate from the parenchyma toward the bloodvessels, never from the blood stream to the parenchyma.

It is important that investigation shall be made as soon after death as possible for the spirochete having marked viability changes its position rapidly apparently invading portions of the body inaccessible during the life of the host. The increase and decrease of the number of spirochetes seems to alternate in wavelike recurrences and to be most in evidence in cases with a stormy course. Death following some acute attack of this nature gives the greatest likelihood of finding of spirochetes. The changes found in the brain are not to be considered the result of this temporary spirochete activity but the result of a repetition of its activity perhaps for years.

Dunlap discusses necessarily without definite conclusion the manner of invasion of the brain by the spirochete and the possibility of a special neurotropic form of the organism as the cause of general paresis. He refers to Ehrlich's theory that the spirochete enters the meninges as well as other bodily tissues at the time of first infection but there is subjected to successive resistance by antibody formation so that the surviving organism which later produces the general paresis has become biologically altered and confined to circumscribed foci. There is no evidence at hand to prove that the spirochete of general paresis is a special neurotropic organism at the start. If it is true that the biologically modified spirochete has a heightened resistance then a modified form of treatment may be necessary for it. It is emphasized that much more attention is due the soil in which the spirochete grows than its possible specifically neurotropic character. This attention to the individual in which this form of syphilitic disorder takes root is quite in accord with the present trend of medicine.

AMEBIC ABSCESS OF THE LIVER

Interesting clinical studies have been carried out recently by Bressot in amebic hepatic abscess and since amebiasis is becoming an autochthonous disease in Europe since the war, the subject is important.

The diagnosis of amebic infection of the liver is difficult on account of the many clinical varieties encountered. Besides the acute hepatitides presenting the classical picture found in textbooks, there are those having a torpid, insidious evolution, while in others the progress of the hepatic infection is concealed by quite different morbid localizations. The absence or the presence of the classical clinical symptoms are not sufficient for affirming or eliminating the diagnosis, as they do not possess the absolute value which observers have attributed to them.

Positive examinations of the feces show the presence of amebæ or cysts in forty-five per cent. of the cases. Out of a total of twenty-five cases, in five there was localized pain in the liver produced by pressure with the hand, in twelve the pain extended to the right shoulder, and in eight there was no pain.

Hypertrophy of the liver is often overlooked in the case of a small abscess, while other than in large pus collections, the enlargement is the result of the accompanying congestions of the organ. Frank icterus is not met with, but a mild yellow tinge of the integuments is not uncommon. The temperature may be high, with marked oscillations, and in some patients it may be normal.

Blood changes are more likely to be absent, the hematological syndrome being variable. However, a marked polynucleosis from seventy per cent. to eighty per cent. appears to be a bad element in the ultimate prognosis. The reaction of urobilin in the urine is not to be relied on, as it is absent in small liver abscesses and is constantly present only in large pus collections.

Radioscopy should invariably be resorted to. In the normal state the diaphragmatic dome is two centimetres higher on the right side, while it may reach from six to ten centimetres in suppurating hepatitis. There are other well known radioscopic signs which may aid in making the diagnosis.

But exploratory puncture is the only means at our disposal for affirming the diagnosis of suppurating hepatitis. In small pus collections several punctures will probably be required until the needle reveals pus. The needle should be at least ten to fifteen centimetres long with a calibre of not less than one millimetre, and if a painful area exists the needle should be thrust in at that point. Otherwise, the entire hepatic region must be explored, not overlooking the posterior region as is frequently done. The characteristic chocolate or brick red color of the pus will eliminate the diagnosis of metastatic abscess, infectious angiocholecystitis, areolar abscesses and suppurating hydatid cysts. The presence of glucose in hepatic pus in an excellent diagnostic element.

The great elements of success in the treatment of hepatic abscess are early diagnosis and surgical intervention. Emetine can prevent abscess formation only when exhibited during the phase of congestion, that is to say, at the very onset of necrosis, and it should be exhibited after the abscess has been opened and drained surgically.

RESTING THE LUNG

Rest is the most important factor in the cure of active disease, but the disease in which rest of the affected organ is most needed—tuberculosis—is, unfortunately, the one in which it is most difficult to obtain. General rest of the tuberculous patient in the recumbent position produces part of its good result by reducing the need for oxygen to a minimum and, so, the frequency and degree of expansion of the lung. The production of an artificial pneumothorax is a bold attempt to give local rest to at least one lung, and it has had a pretty thorough trial. It has proved of great benefit in a considerable percentage of selected cases where careful technic was employed. There is frequent complication by pleuritic effusion or by empyema, but in desperate cases these risks are worth taking. Another disadvantage is that the treatment must be carried out over a long period of time with instillations of air every ten days or so. Then, the presence of adhesions in the pleura may interfere, and need to be severed before collapse of the lung is accomplished. Altogether it is a most troublesome method, even in skilful hands.

The resection of a piece of a few ribs, or of all of them, on one side, with or without compression of the apex, additionally, by tucking a part of the pectoral muscles into the thorax, has accomplished much in some cases.

Lately, a new method of resting the lungs, or, presumably, the apices of the lungs, has been suggested —that of diaphragmatic and infrequent breathing. It is possible for one to reduce the number of his respirations from sixteen a minute to as few as four or five. Probably little is accomplished by this reduction in rate, since, when one does breathe, he must take in a proportionately greater amount of air, but in this new treatment the patient is instructed to control the upper respiratory muscles and uses only the diaphragm.

In practice such breathing is tried at intervals for short periods, increasing the socalled dose day by day. It requires good teaching, and much will power on the part of the patient, but it is at least of advantage in that it gives the patient something to do, and this means everything to the bedfast sufferer from tuberculosis.

Diaphragmatic breathing doubtless gives the apices some rest, but whether the infrequency has any advantage is not so apparent. Certainly this new treatment will do no harm, and it would seem to be of benefit to practice diaphragmatic breathing with or without reducing the number of respirations. Many sanatoria are now trying this new means of cure, or contribution toward a cure, and the results will be looked for with great interest.

THE UNITED HOSPITAL FUND—WHAT IT IS AND DOES

The United Hospital Fund of New York, formerly the Hospital Saturday and Sunday Association of New York City, was organized in 1879. This organization was the first recognition of the unified character of the city's hospital problem, and, to help solve it, the fund has enlisted the cooperation of people of every race and faith. The total sum received from the people of New York for support has been, from the beginning, $6,044,787.22.

In 1879, the fund contributed to nineteen hospitals, with a total for the year of 8,688 patients. Today, the fund comprises fifty-eight hospitals, with 195,281 patients. Its object and present activities are: to raise money with the least cost for hospital free work; to distribute it wisely and impartially among the hospitals; to promote high standards of administration and accounting; to collect and publish full and uniform statistics of the work and finances of hospitals; to secure free treatment for proper hospital cases; it has a committee on dispensary development; it maintains a Hospital Information Bureau.

All hospitals sharing in the fund are required to submit an annual statement showing in detail the work, income, and expenses of the hospital for the preceding year. These records are published and kept on file. Contributions are secured by volunteer committees of men and women from more than three thousand contributing firms; publications are distributed in letter and leaflet form; collections are taken in churches and synagogues on one Saturday and Sunday a year; contributions are made by many benevolent orders and societies. The distribution of these collections is made under the direction of a special committee without regard to race or creed, and the amount is based upon the number of days of free hospital treatment given by the institution during the year, combined with the daily cost of ward patients. The quality of hospital management is also taken into consideration.

At present, fifty-eight of the leading, nonmunicipal hospitals of the city belong to the United Hospital Fund, and each is entitled to one representative. The contributing public is represented by forty-eight members at large, elected by the trustees for a term of three years. These representatives, combined with the members at large, constitute the corporation, and elect from their number at each annual meeting a board of trustees, which is charged with the management of the organization.

Any hospital of Greater New York may, upon application, become a member of the fund after recommendation by the committee of admissions as to equipment and management, and subsequent election by the board of trustees, provided that it is duly incorporated; that it has had for three years not less than thirty-five ward beds; and that it has given during the same period not less than five thousand days of free service a year. Hospitals falling below standard forfeit their membership.

DEATHS OF CHILDREN FROM ACCIDENTS

During 1921, 3,483 persons died in New York City from injuries received in accidents. The heaviest mortality was between the ages of five and fourteen, in other words, at the ages when children use the streets most for play, and when they are least careful. The death rate during this period of life was thirty-one to the one hundred thousand. The only age at which the rate exceeded this, was over sixty-five years of age, where the rate was fifty-one to the one hundred thousand. The total number of deaths, however, of persons over sixty-five was less than one third of those between the ages of five and fourteen. It has been found that the largest number of street accidents occur between three o'clock in the afternoon, and six in the evening, when children are playing in the streets, and when people are going home from business or shopping.

During 1921, 864 persons died as a result of falls, 138 of these from fire escapes or windows. Almost one third of these latter deaths were those of children under five years of age. Burns and scalds were another important cause of deaths, and of these almost half of the deaths were those of children under five. Mortality from drowning increases steadily from the fourteenth to the twenty-fifth year. In 1921, fifty-three boys between the ages of five and fourteen were drowned in waters surrounding the city. The figures quoted show only a small amount of the suffering caused by accidents, for the statistics give only accidents resulting fatally. There are probably from ten to thirty times as many more accidents that do not result in death, but which cause long and painful suffering and often leave the victim permanently incapacitated. The indications are that most accidents result from carelessness, and that if children can be educated, as soon as they begin to walk, to exercise care, this terrible waste of life may in some measure be prevented.

News Items.

International Society of the History of Medicine Meeting.—At a meeting of the permanent committee of the International Society of the History of Medicine, held at Antwerp on April 11, 1923, it was voted to hold the fourth International Congress of the History of Medicine at Geneva, Switzerland, during the third week of July, 1925. The following officers were elected: President, Dr. Charles Greene Cumston, Geneva; secretary general, Dr. A. de Peyer, Geneva (Rue Général Dufour, 20); honorary president, Sir D'Arcy Power, London; honorary vice-presidents, Dr. Edward B. Krumbhaar, Philadelphia, and others.

Dr. Wolbarst Office Removal.—Dr. Abr. L. Wolbarst announces the removal of his office to 114 East Sixty-first Street, New York City.

Army Medical and Dental School Commencement.—The closing exercises of the Army Medical School and the Army Dental School session of 1923 will be held at the Auditorium, New National Museum, Washington, D. C., Friday afternoon, June 8th, at two o'clock.

Dr. Edward Canizares Commemorated.—The Department of Health of the City of New York has passed a series of resolutions commemorating the death of Dr. Edward Canizares, hospital physician at Riverside Hospital. Copies of the resolution have been included in the minutes of the Medical Board of Riverside Hospital.

New York Hospital Society Urological Department Reception.—Several hundred patrons of the Society of the New York Hospital were guests at a reception of the urological department of the institution, held in the governors' room on May 13th. Dr. Oswald S. Lowsley, the director, explained the important work this department was doing and told of plans for extending it.

International Congress to Meet in Rome.—On May 28th the permanent committee of the Congrés International de Médecine et de Pharmacie Militaires met in Rome, Italy, at the Military Hospital. Following this the second congress held its formal sessions. The congress was held under the patronage of the King and Queen of Italy, who, with Premier Mussolini, received all the delegates.

Dr. Schloss to Return to New York.—Dr. Oscar M. Schloss, formerly professor of pediatrics at Cornell University Medical College and during the past two years head of the department of pediatrics at Harvard University, will return to New York next fall and resume the chair of pediatrics at Cornell University Medical College and the directorship of the service at the New York Nursery and Child's Hospital.

Mt. Sinai Neurological Wards Endowed.—The new neurological wards of Mt. Sinai Hospital, forty beds, endowed by Messrs. Samuel and Harry Sachs, were opened on May 1st. In view of the serious shortage of beds for mental and neurological cases in New York hospitals, referred to in the report of the public health committee of the New York Academy of Medicine, the profession should welcome the endowment of these free beds.

American Psychopathological Association Annual Meeting.—The thirteenth annual meeting of the American Psychopathological Association was held in Boston, Saturday, June 2, 1923, at the Boston Medical Library, 8 Fenway. Contributors to the program were Dr. C. P. Oberndorf, Dr. Gregory Stragnell, Dr. Adolph Stern, Dr. A. A. Brill, Dr. Edith R. Spaulding, Dr. Thomas W. Salmon, Dr. Lightner Witmer, Dr. L. Pierce Clark, Dr. Morton Prince, Dr. Tom A. Williams, Dr. Harold I. Gosline, Dr. Isador Coriat, and Dr. Cornelius C. Wholey. A subscription luncheon was served at the Harvard Club at one o'clock.

Ninth National Chemical Exposition.—The Ninth National Exposition of Chemical Industries is to be held in the Grand Central Palace, New York, during the week of September 17, 1923.

Influenza in Alaska.—An epidemic of influenza exists among natives on the western Alaskan coast, officers of the United States Coast Guard cutter *Haida* reported upon arrival of the vessel here on May 12th in the course of her annual patrol of the Behring Sea.

Dr. Myers to Open Clinic.—Dr. Alonzo Myers announces the association with him in the practice of orthopedic surgery of Dr. J. Stuart Gaul, recently of Walter Reed General Hospital. They opened a clinic on May 15, 1923, at 8 West Seventh Street, Charlotte, N. C., to be known as the Alonzo Myers Orthopedic Clinic, Inc., with complete departments of physiotherapy, brace making and fitting and orthopedic equipment.

Gives Brain of Boy Genius.—The Department of Neurology of the University of Chicago received a unique gift. It is the brain of little Richard Maquiling Thompson, the four year old son of Dr. Thomas M. Thompson, professor of psychology at Colgate University, Hamilton, N. Y. The child, who was endowed with a remarkable mentality, was drowned in the lake on the Colgate campus. Richard's intelligent quotient as determined by the Stanford-Binet mental tests was between 160 and 165. The body was cremated and the ashes strewn over the university campus. The wonderful brain, however, was preserved, and was sent immediately to the University of Chicago.

Deaths in Week Drop 108 From Same Period in 1922.—There was a decrease equivalent to a saving of 108 lives in the deaths reported during the week of May 14th, as compared with the deaths of the same week last year, according to a report made to Health Commissioner Dr. Frank J. Monaghan by Dr. William H. Guilfoy, registrar of the health department. The total deaths reported were 1,423. The principal decline was shown in deaths from bronchial pneumonia. There were eighty deaths from this cause last week, while in the corresponding week last year there were 114. Of the contagious diseases the largest decrease was in diphtheria. There were twelve deaths from this cause last week compared with thirty-four a year ago.

Chicago Council of Medical Women Organized.—In order to collate valuable clinical experience and to promote fellowship, another medical society has been organized, the Chicago Council of Medical Women. Membership is restricted to women holding a license to practise medicine, and the council is limited to seventy-five active members. The incorporators are Anna E. Blount, Alice Conklin, Effa V. Davis, Mary E. Hanks and Lena K. Sadler. The management is represented by Anna E. Blount, president; Mary E. Hanks and Annie White Sage, vice-presidents; Lena K. Sadler, secretary; Eliza R. Morse, treasurer; Alice Conklin, Effa V. Davis and Helga Ruud, directors; Sarah M. Hobson, editor. Eighteen charter members are enrolled.

LONDON LETTER

(*From our own correspondent*)

London, *April 17, 1923*.

PERIL OF THE PEDESTRIAN.

Street accidents have greatly increased in this country within recent years. During 1922 there were seventy thousand accidents in the streets of Great Britain, seven thousand five hundred more than during the previous year. What are the causes of this increase? Is the greater proportion of them due to the carelessness of those who walk or to the indifference of those who drive? A large number of persons, of which the writer is one, believes that the push bicycle provides the most potent peril to the pedestrian. It comes on one silently and from nowhere. A motor cycle can be heard plainly, in fact every kind of vehicle motor driven or horse drawn can be heard, but not the silent push bicycle. It is governed by no rules of the road, comes hurrying along, often far too fast, sometimes on the wrong side of the islands of refuge, dodging in and out of the traffic and a continual source of danger to persons stepping off the curb. Every pedal bicycle should carry a bell which should be rung without cessation. Bicycles have increased in number enormously during the past few years. In 1915 there were under four thousand in this country, in 1919 there were nearly six thousand, in 1920 more than eight thousand, and in 1921 about eleven thousand. Speaking in a general way the cause of accidents is more often than not the fault of those on foot, and these accidents mostly happen either to the old, who are perhaps deaf and whose sight is defective, or to young children who do not realize the danger. However, there is no doubt that motor vehicles are often driven too fast, and in roads or streets in which there is a considerable amount of slow heavy traffic as well, the risks of accidents are intensified. When approaching a crossing there should be no overtaking of one vehicle by another. The perils of the streets are great and traffic should be organized in London and other big cities more systematically than it is at present.

MEDICAL POSTGRADUATE STUDY IN LONDON.

At a meeting of the Fellowship of Medicine held on April 13th last, at the house of the Royal Society of Medicine, a scheme was brought forward by the nonundergraduate hospitals in London which it was decided to accept and take immediate steps to put into operation. The scheme is devised to meet the needs of two distinct classes of postgraduate students, namely, those who require short general courses to refresh their knowledge and those who require advanced courses in the special departments of medicine and surgery. It is proposed to arrange the short refresher courses on the group system, centred in a general nonundergraduate hospital affiliated with certain special hospitals in its neighborhood, and that each group should be responsible for three or four such courses during the year. It is hoped that four or perhaps five of these groups will be founded in London. The program will be begun by a course at the Prince of Wales' General Hospital, Tottenham, assisted by the special hospitals belonging to the Northeastern Group, from June 11th to June 23d. Further details regarding this course and others to follow throughout the year will be published shortly. For graduates who require more advanced instruction it is proposed that each of the special hospitals should undertake two or three courses during the year and in these it is hoped that specialists from the undergraduate hospitals will be willing to come to the special hospitals on the invitation of the staff and assist in lectures and demonstrations.

THE INFANTS' HOSPITAL, LONDON.

The annual report of the Infants' Hospital, Vincent Square, Westminster, London, has just been issued. Six months or so ago Dr. Eric Pritchard was appointed director of this hospital and is thoroughly reorganizing its management. When he was given this post in June last, one half of the inpatient accommodation was closed down and the outpatient attendance had fallen to between two hundred and two hundred and fifty a month, compared with three hundred to three hundred and fifty in the previous year. Already the efforts of the new director and staff have been attended with much success, and it is hoped to make of the hospital a postgraduate medical centre for London where infants' diseases and nutrition can be studied clinically and from the laboratory viewpoint under most favorable conditions. The hospital is well built and arranged both as regards its inpatient and outpatient departments, and splendidly equipped. It contains public ward accommodation for twenty-five infants and isolation wards for eighteen, and excellent facilities for open air treatment. The outpatient department is spacious and contains a magnificent research laboratory. The object of the director is to make of it, in addition to an institution for the treatment and care of infants, a training school for students, postgraduate and undergraduate, and for nurses and those engaged in infant welfare work. It is intended for infants of the necessitous poor and Princess Mary has consented to become president.

COORDINATION NEEDED AMONG HOSPITALS.

There are more than one hundred hospitals in London, most of which are full and some of which have long waiting lists. At the present time there is frequently found to be a considerable amount of difficulty in gaining admittance for a patient, even if dangerously ill and requiring immediate hospital attention. It is said to happen with undesirable frequency that patients are carried from one hospital to another before room can be found for them. When they are finally admitted, it is obvious that a great deal of valuable time has been wasted and no doubt it happens that in this way lives are forfeited every day. It is suggested in a London evening journal by a hospital superintendent that it would facilitate matters greatly if an inquiry bureau were formed under the direction of the London County Council. It is pointed out that some of the advantages of this plan would be as follows: 1. It would coordinate the work of hospitals, and in urgent cases it could be stated promptly at which institutions there were vacant beds. 2. It would organize and control a complete ambulance service. 3. It would give specialized advice on health and hospital questions generally. There is a lack of coordination among the London hospitals and it is suggested that reforms in this direction come well within the province of the Ministry of Health.

THE ROCKEFELLER FOUNDATION AND THE SCHOOL OF HYGIENE.

The further steps necessary in regard to the formation of the School of Hygiene, for which the Rockefeller Foundation has promised to provide the necessary funds for construction, have been discussed between representatives of the Ministry of Health, the University of London and the Foundation. It has been decided to set up at once a Transitional Executive Committee to arrange for coordination with other authorities presently operating in the same or similar spheres; to evolve the organization of the School of Hygiene in detail; and to develop detailed plans of the School of Hygiene to such a point that construction can be actually begun by them. It is also proposed to appoint provisionally a director of the school who will act in an advisory capacity to the transitional executive committee, and the foundation has undertaken to provide a sum not exceeding four thousand pounds a year towards the salary and the expenses of the director. The Minister of Health has under consideration the question of the personnel of the transitional executive committee.

PLAGUE IN INDIA AND THE POISONING OF RATS.

A correspondent of the *London Times,* April 17th last, gives it as his opinion that the poisoning of rats is dangerous in the case of plague. A rat from a plague infested house is a source of danger when it dies, as the rat flea leaves the cold carcass and searches for another warm blooded host. The plague is conveyed by the rat flea which is not a source of danger until the rat is dead. Alive, the fleas prefer it to another host. In a successful campaign waged against plague in India rewards are only offered for live rats. The rat traps were cages and when full the rats were immersed in a weak solution of mercury bichloride. This disinfected the cages as well as drowning the rats. The cages were then shaken over small wooden boxes partly filled with jute waste. The dead rats fell into these boxes, and the fleas could be seen snuggling into the dry tow. The boxes were then thrown into furnaces and consumed.

A CRISIS IN INSURANCE PRACTICE.

The present agreement with regard to the per capita payment of panel practitioners, namely nine shillings and sixpence, about $2.40, ends soon when a crisis in the working of the National Insurance Act will be precipitated. A great deal of discontent on the part of the insured has been manifested for some time and, moreover, the approved societies are clamoring for a share in the administration of the act. They argue that if they pay the piper, they do this partly, they ought to call the time or, at least, have some voice in calling the time. It is believed that rather than give way to the approved societies or rather than let these societies have their own way, efforts will be made to induce the Government to repeal the act.

A TEXTBOOK OF PHARMACOLOGY AND THERAPEUTICS.

An English edition of a textbook of pharmacology and therapeutics, by Dr. E. Poulsson, professor of pharmacology in the University of Christiania, edited by W. E. Dixon, M. A., M. D., F. R. S., reader in pharmacology, Cambridge, has just been brought out by William Heinemann, Ltd., London. Those parts of this subject of the first importance are dealt with and the more recent valuable contributions. In the main the pharmacological system developed by Schmiedeberg is followed. There is room in the English language for a work planned in this way. It is excellent in all respects.

DEATH OF DR. ARTHUR LATHAM.

Dr. Latham died on April 13th last, in a nursing home in London. Dr. Latham was one of the best known physicians in London and one of the most loved and respected. He specialized in tuberculosis, of which disease his knowledge was profound and catholic. He was educated at both Oxford and Cambridge and was physician and lecturer on medicine at St. George's Hospital, London. In addition he held numerous appointments in smaller hospitals, and was senior assistant physician to the Brompton Hospital for Consumption. He won the first prize of five hundred pounds for an essay on the erection of King Edward VII Sanatorium. He was a frequent writer to the medical press and the author of several works.

NEW MINISTER OF HEALTH.

Mr. Neville Chamberlain, the new Minister of Health, by heredity and training should be well fitted for the position. He is a son of Joseph Chamberlain, formerly minister to Great Britain. Mr. Neville Chamberlain received his training in the same hard school as his father, in the municipality of Birmingham. However, the present minister has a rough road to travel. His position is quite the reverse of a bed of roses. The housing problem simply bristles with difficulties and that alone will occupy the greater part of his time. But the insurance scheme requires amendment, lunacy reform is called for, and Lord Athlone's report on postgraduate education should not be passed over. Mr. Chamberlain will have plenty of opportunity for the exercise of those great business qualities of which he has already shown himself to be possessed.

SMOKE ABATEMENT.

Our large cities continue smoky and dingy although better in these respects than formerly. In addition to being unesthetic, a smoky, dirt laden atmosphere is unfavorable to health. We are truly a conservative people. We even cling to our dirty atmosphere because we are used to it and perhaps, the necessary alterations to abolish it are not made, because the authorities do not wish to antagonize the big manufacturers by insisting that they take steps to do away with the nuisance. The question is asked, Why should other industrial countries be compelled to take such steps? If drastic repressive legislation in this direction can be enacted and carried out in these countries why not in Great Britain? The onus of discovering the means for suppressing factory smoke should not be thrown on the Government, as has been suggested here, but associations should be formed to maintain scientific experts who would advise and assist its members in the economic use of fuel. The Smoke Abatement Committee suggested that the Ministry of Health appoint one or more scientific fuel experts who would consider cases in which exemptions were applied for, and to bring pressure upon a defaulting local authority. If a clean or fairly clean atmosphere can be obtained in Pittsburgh, it should be possible of attainment in London.

VIENNA LETTER

(*From our own correspondent*)

VIENNA, *March* 30, 1923

(*Continued from page* 633).

These people have entirely lost their sense of duty. I once sat at dinner with close friends of my boyhood days. The question arose as to whether or not a man named A. should pay some debt he owed to B. I remarked, "Why, certainly he should, provided he has the money to pay it with." "Oh, no, excuse me, dear doctor," interjected a man I have all my life considered honest.

"A. should pay only if B. is in need of the money." All my arguments to the effect that it was A's *moral* duty to pay an honest debt, provided he had the money, failed to convince my friend of the utter baseness of his conception. I grew so vexed, indeed, that I left the dinner party. On my way home, I asked my own brother in law, a prominent physician, in utter despair, if he thought me in the wrong. He replied, "You see, the people here now do to each other, individually, what the government has done to them collectively. The government borrowed money from them in the form of war loans and refused to pay it back." Then it was that I understood. The war, with its hideous lies, has annihilated the people's sense of right and wrong.

And how should medical men, even the leaders in the profession, remain free from that contamination? There is no sense of duty at the clinics either. The assistants—many of them teaching professors, of international reputation before the war—have lost their idealism, their devotion to research work. They look hungry, starved, and ill clad; their clothes have been turned inside out because they can't afford to buy new ones, their shoes are worn out, their shirts torn. One of them told me that he hardly averaged more than one consultation a day. He cannot feed and clothe his wife and three children on such an income.

In this connection, I wish to repeat a dialogue I had with one of the clinical chiefs. He said, "Doctor, you are the chairman of the American Medical Association of Vienna. Truly, I don't like to see the young American doctors come over here and take up all the time of our assistants by asking for courses. Our assistants then have no time left for research work. We rather want men to come over here to do research work." "Well, chief," I replied, "don't you think an assistant is better off if he earns sixty dollars a month—a sum sufficient to cover the total living expenses of himself and family—by teaching one hour a day, and still has twenty-three hours out of the twenty-four left for doing research work, than if he sat all day nervously at the clinic and listened to the telephone, to snatch a few consultations which cannot, at best, bring him in enough money to keep him merely alive?" "Well," answered the professor, "perhaps you are right. I never thought of it that way." This same chief never makes the rounds of his wards. At least I never saw him make any during half a year's stay at his clinic. Clinical chiefs, in prewar times, did not shirk their duty in this way. Nothnagel always found time to make the rounds with his assistants and pupils every day, thus giving them valuable information and inspiration. The assistants of the above mentioned chief informed me that he made the clinical rounds only once a year—at Christmas, when all the patients get their little Christmas gifts.

The clinics are very poorly equipped; there is no soap nor any clean towels in the ward rooms if you wish to wash your hands after handling the patients. Owing to the lack of proper food supplies, the once famous dietary kitchen has been entirely abolished. Professor Salomon, the genius "cook" and former assistant to Professor von Noorden, has left Vienna for South America. (His chief, von Noorden, had resigned from the chair of internal medicine even before the war because, as I understand, he was disgusted at the nagging attitude of the government, as well as his fellow professors.) The one thing which I intended to take up, in Vienna, was dietary cooking; for the reason mentioned, there was no possibility of carrying out my plan. In this connection it may be interesting to note that I searched for months, in all the internal clinics, for a dietary nurse who could supervise the kitchen of one of my rich friends, a diabetic. Such a nurse did not exist over here! Compare with this your wonderful diet nurses, educated at the clinics of Allen, Jocelyn, at the Rockefeller Institute and many others!

Still, the leading professors don't believe they can learn anything on medical lines from their American colleagues, and they as well as the intellectual public of Vienna—whenever their attention is called to the necessity of learning the more advanced ways of Western nations—are ready with the stereotyped reply, "If we really are not superior in everything medical, why do you Americans come over here to learn from us?" The rejoinder, that every successful American owes his success to his being ever ready to learn from others and to adopt the things he finds better among his neighbors, whoever they may be, does not convince those who do not wish to be convinced—and that is the majority among them. Psychologically, this atitude is easily understood. The only thing left to them, the *one* thing the horrible war could not take away from them, is their old culture, as they term it; or their antiquated culture, as I should like to call it, and they cling to it with the superhuman tenacity of a drowning man clinging to a piece of driftwood, to the débris of the wreck of a formerly gorgeous ship.

The equipment of the clinics was, as I said before, very inadequate. Sheets, bedding, instruments, alcohol and chemical reagents were, to a large extent, supplied to the hospitals by the American Red Cross—the government not having any money for the purpose. While I worked at the clinic, I bought my own chemicals and paid large tips to the *Diener* to have my chemist get decent service.

A lawsuit recently brought against one of the nurses of the dermatological clinic of Professor Riehl throws some light on the state of affairs (July 18, 1922). The nurse was accused of having handed to the surgeon operating on an eight year old boy, for lupus, a bottle containing mercury bicyanate instead of cocaine for hypodermic use. The physician in charge of the clinic, Professor Arzt, declared in the witness box that owing to the terrible want and poverty at the hospitals, the various preparations were not kept in the proper bottles, and that was the reason why the nurse mistook one bottle for the other.

The cases coming to the hospital are not of the variety we used to see before the war. This may easily be understood if we consider the fact that the hospitals formerly used to draw their patients from a population of fifty millions, inhabitants of the old Austro-Hungarian Empire, whereas now there are only six millions of inhabitants contributing to the sick material of the Viennese hospitals. The detached States, Czechoslovakia, Hungary, Jugoslavia and Poland have established their own clinics, and they do everything possible to make the journey to Vienna a great nuisance. They have established or enlarged universities of their own, and try to convince their inhabitants—they have fairly succeeded in doing so—that their own clinics and hospitals are just as good, if not better.

The wonderful, large Viennese institutions for chemistry, biology, physiology and neurology are to a great extent deserted, or kept partially going with the help of foreign donations (Rockefeller Institute, etc.). The government sees itself compelled to reduce the number of peripheral hospitals, as well as some of the departments of the main hospitals, owing to lack of funds and the decreasing number of patients. The great Anatomical Institute, once the pride of Vienna when Hyrtl, Zuckerkandl and Toldt were its chiefs, is well on the way to meet the same fate. The regular State subsidy amounts to six hundred thousand kronen, the State contribution to the burial of corpses five hundred thousand—altogether about one million kronen a year, that is, fifteen dollars (!!) The rest of the expenses must be met by charitable contributions (Rockefeller Institute, Switzerland, etc.). The subsidy for its library consists of two hundred thousand kronen—three dollars (!!) Think of the number of foreign magazines that can be subscribed to with such a sum!

The yearly contribution to the renowned Anatomical Museum consists of three thousand kronen—just enough to buy half a loaf of bread. The linen, instruments, mikrotom, apparatus, etc., have been contributed—here, again, by foreign countries. The worst drawback is the fact that there are not enough corpses. The institution receives only fifty corpses a year from the hospitals, and these are just sufficient to supply the needs of the native students. There are altogether about seven hundred of the latter, while there are over seven hundred students of other nationalities trying to get to the twenty-four dissecting tables of the institution (Jugoslavs, Bulgarians, Roumanians, Greeks, Turks, Russians, Egypians, Chinese, Japanese and—Americans)! If it were not for the fact that Hochstetter and the genial Tandler manage to keep corpses for a year under carbolic acid, in the big troughs in the basement, it would be utterly impossible to accommodate that number of students. If one stops to think, however, that it takes ten tons of carbolic acid a year, that is twenty-five million kronen worth of carbolic acid to do this alone, the ever loud cry for corpses for anatomical studies may be easily understood.

The American colleagues who came over here for postgraduate work in surgery were more or less disappointed; they could not learn much about technic by watching the operator from their benches. A few of them succeeded in getting the position of first assistant to one of the professors of surgery at some of the peripheral hospitals either by paying a good fee to the professor or "making a liberal contribution to the hospital fund," as they termed it. The law forbids any foreigner to operate on the living, though a few Americans did succeed in performing some nose, ear, or throat operations on the living by secretly paying a fee to the surgeon in charge. On the whole, the men attending the courses in eye, ear, nose, and throat were satisfied with the clinical part of their work, but thought that the operative technic was superior in the United States.

The visiting physicians were more satisfied with the work they got in heart diseases. Professor Wenckebach's assistant, Professor Winterberg, is in charge of the department for heart diseases and makes electrocardiagram his hobby. Professor Kaufman, in charge of a heart station comprising thirty beds (which originated during the war and is still kept open by means of charitable contributions) is an excellent teacher of the old Nothnagel school, and he gives first rate courses for general practitioners. Professor Finsterer, an artist in abdominal local anesthesia, is admired for his stomach resections. Professor Wagner's clinic for nervous and mental diseases has large material. His new treatment of paresis (by means of intravenous injections of malaria tertiana blood) is most efficient. Syphilis of the central nervous system may, however, be better studied at the Nonne Clinic at Hamburg or at the Vanderbilt Clinic in New York than over here. Urology (cystoscopy, etc.) is well represented by Professor Blum, Dozent Pleschner, Dr. Bachrach and the former assistants of the late Professor Zuckerkandl. Dermatology, as taught by Professor Ehrman—one of the few really scientific workers—is quite in favor with the American doctors, as is also Dozent Stein and Oppenheim. Professor Ehrman's department will, unfortunately, soon cease to exist, sharing the fate of a few other departments which the government, compelled to reduce expenses, has decided to abolish. Many of the laboratories stand empty owing to lack of chemicals, fuel and light.

The sharp reduction in all expenditures has worked havoc with most of the scientific institutions in Vienna. A few weeks ago, for instance, two large laboratories in the stately Chemical Institute had to be closed, and about seventy students were compelled to be idle, because one of the laboratory servants was taken sick and there was no one to fill his place. The students dug into their own pockets to raise money—about two million kronen a month—to pay the wages of another servant who had been discharged by the State. Assistants and students waste a great deal of their time in doing the menial work of their laboratories. There are no servants to be had for purely scientific research work.

Ehrman, chief of the department for dermatology, Frisch, chief of the department for internal diseases, and Foederl, chief of the surgical department, were notified last December that they were to be "reduced." Men in their best years, of international scientific reputation, who have been the teachers of generations of physicians all over the world, fall victims to this indiscriminate reduction policy.

(*To be concluded.*)

Book Reviews

THE PIRQUET METHOD OF FEEDING

Auf Grundlage des Pirquetschen Ernährungssystems. Die Ernährung Gesunder und Kranker Kinder. Von Privatdozent Dr. Edmund Nobel. Wien, Leipzig, München: Rikola Verlag, 1923, pp. 74.

Heretofore the physician was compelled to seek the data for feeding a healthy or sick child at various sources. In this monograph the author, after many years of experience as a teacher and physician, has endeavored to present the new theory of nutrition in as simple a manner as possible. The Pirquet system of feeding has become quite popular abroad. With a suitable dietotherapy many cases of disease may be successfully treated and frequently an expensive drug therapy may be eliminated. This system of feeding is based on the physiological nutritional unit of milk instead of the purely physical calory: one gram of standard milk is the metric nutritional unit and is called a nem and from this the nutritional value of the various foods are calculated, both raw and when cooked or prepared. The required amount of food in a given case depends upon the linear distance between the scalp and the buttocks, with the patient in the upright sitting position: the cube of the sitting height equals ten times the body weight in grams, from which the nutrition surface is calculated. In this way the amount of food required at each meal, for one or more patients, may be estimated. After discussing the theory of this system of feeding, the feeding in the following conditions is discussed: pregnancy and lactation; the healthy and sick child; artificial feeding; heat prostration; prematurity, malnutrition and vomiting; enuresis nocturna, Barlow's disease and xerosis and keratomalacia. Directions for the preparation of vitamine containing fruits and vegetables are given.

A TEXTBOOK ON RECTAL DISEASE

Diseases of the Rectum, Anus and Colon. Including the Ileocolic Angle, Appendix, Colon, Sigmoid Flexure, Rectum, Anus, Buttocks and Sacrococcygeal Region. By Samuel Goodwin Gant, M.D., LL.D., Professor and Chief of the Department for Diseases of the Colon, Rectum and Anus at the Broad Street Hospital Graduate School of Medicine, etc. With 1128 Illustrations on 1085 Figures and 10 insets in Colors. Volumes i, ii and iii. Philadelphia and London: W. B. Saunders Company, 1923. Pp. ix-543, 545 and 528.

The author has produced a comprehensive textbook, which is characterized by clearness and attention to detail and which is the last word in this branch of medicine. It is of value to the specialist and the general practitioner, taking up every aspect of the diseases of the lower intestinal tract and devotes more attention to diseases of the gastrointestinal tract than any other treatise published heretofore. Office treatment, both medical and surgical, is stressed. The illustrations are of large size, very apt and abundant; the colored plates are beautiful. The reading is easy owing to the large and clear type and the arrangement of the material is such as to render it of great value as a work of reference. This is the latest and best book on the subject.

The first volume deals with the rectum and anus, including the embryology of the gastrointestinal tract, the anatomy of the rectum and anus, the diagnostic significance of anorectal symptoms, the examination and diagnosis of the gastrointestinal tract and buttocks, and the relation between anorectal and other diseases. The various methods and kinds of anesthesia and their technic, including general, spinal, paravertebral, sacral, extradural, caudal, regional and local infiltration with the various anesthetics are discussed. The malformations and anomalies of this part of the anatomy are described. Wounds and injuries, inflammations and fissure in ano are discussed, with special attention to the common conditions of anorectal fistula and hemorrhoids. The relation between pulmonary and anorectal tuberculosis to fistula in ano is explained.

The second volume takes up the subjects of hemorrhage, procidentia, ulceration, pruritus, perianal skin affections, tuberculosis, esthiomène, venereal diseases, abnormal sexual practices, stricture, cysts, diverticula and tumors; also the anatomy and physiology of the colon and ileocolic angle and the various forms of colitis.

The third volume includes infections and diverticulitis of the colon and ileocolic angle, focal infections, tumors, hemorrhage, constipation and obstipation. The chapter on constipation gives the medical treatment in detail, including also the various methods of physiotherapy; that on obstipation contains detailed descriptions of the various operative procedures used. The various operations on the lower intestinal tract, with their advantages and disadvantages, are discussed in full. A special chapter is devoted to the colonic, sigmoidal, rectal and anal diseases encountered in infancy and childhood.

SKIN DISEASES AND METABOLISM

Stoffwechsel und Haut. Grundzüge zu einer dynamisch-energetischen Stoffwechselpathologie und therapie der Hautkrankheiten. Ein Beitrag zur Pathochemie des Blutes. Von Dr. Erwin Pulay. Berlin, Wien: Urban and Schwarzenberg, 1923, pp. xvi-240.

There are many theories regarding the relationship between disturbances of the internal organs and those of the skin. The author endeavors to build a solid foundation for dermatology with the aid of chemistry of the blood and tissues; the field of therapy will, no doubt, be enriched with the supplemental application of pathology, clinical chemistry and study of clinical phenomena. The former methods of studying skin diseases microscopically, bacteriologically, pathologically and morphologically have imparted a certain onesidedness to dermatology, with the result that great advances were made but at the sacrifice of the relationship of skin diseases to the body as a whole; dermatology lacked the dynamic point of view. Skin diseases may be divided into two groups: the dermatoses caused by specific excitants in the skin (infectious diseases) and those resulting from possibly unknown processes of a functional nature in other organs—toxicodermias or dermal anaphylactic phenomena. In order to determine the relationship between disturbances of the internal organs and the skin changes, the author utilized the pathological chemistry of the blood.

It has been shown that every retention of substances in the blood runs parallel with such a retention in the tissues. This leads to the therapeutic endeavor to treat skin diseases with the biological remedies, such as proteotherapy, calcium therapy, and colloid therapy. To do this intelligently the deviation from the normal chemistry of the blood must be understood. Constitutional factors must also be taken into consideration, as the appearance of an organism depends upon two factors: the structure of the germ plasm and the external factors active during development. This may be done in two ways: clinically, by classifying the different dermatoses according to constitutional types, thereby establishing a relationship between the skin changes and other organs, or by accurately determining the individual constitutional types and differentiating them more sharply. The chemical and physicochemical theories of cell function and the dependence of this function upon changes in the condition of the cell have also had their effect on dermatology—in fact, a great advance has been made by determining the close relationship between the blood and the skin in metabolism.

The author then discusses the following blood elements and metabolic conditions: the coagulation of blood plasma, the serum, acidosis, ionization, hemoglobin, osmotic concentration and electrolytic balance, specific gravity, dry substance and water content, the pathology of water metabolism, tumescence and detumescence, the metabolism of nitrogen and albumin, sugar, carbohydrate metabolism, lipemia, cholesterin, uric acid and purin metabolism, chlorides and sodium, calcium metabolism, the action of electrolytes and the nervous system, internal secretion and blood chemistry, blood chemistry and consitution, light and its effect on living matter and colloid therapy.

Clinically, the author shows that the morphological changes in the skin may be explained physicochemically as phenomena of tumescence and detumescence and he explains the clinical phenomena of various skin diseases in the light of metabolic changes. The methods of examining the blood and the estimation of its constituents are detailed. The blood changes encountered in various skin diseases are tabulated for easy reference.

The dermatologist who reads German will not want to be without this book, which lays the foundation for a new and more expansive outlook in dermatology.

DISEASES OF CHILDREN

Diagnostik und Therapie der Kinderkrankheiten. Mit speziellen Arzneiverordnungen für das Kindesalter. Ein Taschenbuch für den praktischen Arzt. Von Prof. Dr. F. Lust, Direktor des Kinderkrankenhauses in Karlsruhe. Dritte, neubearbeitete Auflage. Berlin und Wien: Urban & Schwarzenberg, 1923. Pp. vii-465.

This is an intensely practical book, devoid of all theory, on the diseases of children, dealing with the essential points in diagnosis, especially of the specifically infantile and rarer disease pictures and the therapeutics of infancy and childhood. It serves well its purpose of a pocket edition for the use of the general practitioner. The book is divided into two parts.

The first part takes up the normal development and measurements of the child, nutrition, diseases of the newborn, constitutional and metabolic diseases and those of the various systems and organs of the body. The diseases of the digestive tract are divided into those of the mouth, pharynx and esophagus, the stomach, disturbances of nutrition with natural and artificial feeding, various intestinal diseases, and those of the liver and the peritoneum. The diseases of the urogenital and nervous systems are also considered extensively. Special chapters are devoted to the infectious and skin diseases. The chapter on therapeutic technic, including physiotherapy, serotherapy and organotherapy, is particularly helpful. The second part gives a list of all the drugs, food, mixtures, remedies, etc., with directions for their preparation and dose. The list is long and intentionally contains many drugs that are not generally used in pediatrics.

TREATMENT OF TUBERCULOSIS

Handbuch der Gesamten Tuberkulose Therapie. By Dr. Ernst Loewenstein. Berlin and Wien: Urban and Schwarzenberg, 1923.

Although entitled a handbook of therapy of tuberculosis, this work is in reality a comprehensive textbook of tuberculosis in all its forms with special emphasis on treatment and prophylaxis. This is as it should be, for rational treatment demands a thorough understanding of the nature of disease and of its pathological anatomy and physiology.

The book is planned with the belief that the hospital and sanatorium treatment of tuberculosis can at best be but a short episode in the course of the individual case, and that the brunt of the management of tuberculosis falls on the general practitioner. There is first a careful presentation of the factors concerned in the healing of a tuberculous lesion, then a short but comprehensive description of the pathology and symptomatology of the disease and, finally, a discussion of treatment in all its forms with great attention given to technical details.

Only the first volume in two parts has appeared at the present writing. This volume includes a statistical study of the incidence of tuberculosis, an excellent chapter on tuberculosis of the bloodvessels, one on the anatomical and clinical forms of pulmonary tuberculosis by Bacmeister. Other sections discuss the principles of light therapy and climatic treatment, the construction of tuberculosis sanatoria, institutional treatment, and a statistical study of the results of sanatorium treatment. There is a presentation by Dr. J. Walsh, of Philadelphia, of the tuberculosis clinics and tuberculosis prevention program of the United States. Five hundred pages are devoted to a discussion of the physiological principles of nutrition with special reference to nutrition in tuberculosis. This includes a review of the physiology of digestion and a detailed discussion of the individual foodstuffs, their preparation and food value. The author, Durig, covers every conceivable aspect of the subject from a discussion of the best cuts of meat and the technic of cooking, to a consideration of the specific dynamic action of protein. In the second volume specific methods of therapy, as well as the treatment of extrapulmonary tuberculosis, will be presented.

The work may possibly be criticized for its wealth of detail. Its value lies in the mode of presentation. For instance, the chapter on light is accompanied by a review of the physics and chemistry of light rays, their biological effects and the physiology of their action. It gives the physician a thorough understanding of the methods which he employs and substitutes rational physiological concepts for blind empiricism, bringing as far as possible the same critical spirit to problems of therapy as to diagnosis and laboratory procedures.

ROCKEFELLER INSTITUTE REPORT

Studies from the Rockefeller Institute for Medical Research. Reprints Volume xliv. New York: The Rockefeller Institute for Medical Research, 1923, pp. 6-610.

This publication is a report of the various activities in the laboratories of the Rockefeller Institute, mostly of a purely scientific nature. In the department of pathology and bacteriology, this number contains a number of articles on experimental epidemiology, which are the initial series of reports on the relation between epidemics among laboratory animals and respiratory borne infections, the disease investigated being mouse typhoid. Other articles deal with the organotropic, bacteriotropic and leucocytotropic actions of certain organic chemicals, the rabbit septicemia bacillus and the etiology of yellow fever. In biophysics, there is an article on mouse typhoid and its control by vaccination. The articles from the departments of chemistry, experimental surgery and general physiology are not of a practical nature. The articles on the hospital work include such practical subjects as the influence of the thyroid upon diabetes by F. M. Allen, the carbohydrate requirement in children by L. E. Holt and H. L. Fales, the treatment of rheumatic fever by H. F. Swift and several others of a less practical nature. There are also a number of articles from the department of animal pathology. They are nearly all reprints from various scientific journals.

LUMBAR PUNCTURE

Die Lumbalpunktion. Anatomie, Physiologie, Technik, Untersuchungsmethoden, Diagnostische und Therapeutische Verwertung. Von Dr. Martin Pappenheim. Wien, Leipzig, München: Rikola Verlag, 1922, p. 184.

This monograph is the result of many years of experience, not only in the practice of lumbar puncture, but also in teaching it to others. It was prompted by the many coarse technical errors resulting from the lack of a complete understanding of the essential points in the various spinal fluid reactions and the consequent varying reports on these reactions in the literature. Certain details in technic are especially emphasized, thus imparting a personal note to the work. Only the most important spinal fluid tests are described, including some which the practising physician cannot carry out himself, such as the Wassermann and hemolysin reactions. Nevertheless the physician should be acquainted with them well enough to be able to evaluate the result, provided he knows the methods used by the laboratory doing the work. Certain simplifying modifications are introduced. After discussing the anatomy, physiology and the source of origin of the spinal fluid and the theoretical significance of the individual methods of examination, much of which is still a moot question, the following tests are described and discussed: the various methods of measuring the pressure and the sources of error, the physiology, properties, chemical construction, pathology, the quantitative and qualitative examinations and differentiation of cells, the various reactions (globulin, Nonne-Apelt, Ross-Jones, Pandy, Nissl and Brandberg-Pfaundler), the various tests for albumin, the coagulation of fibrin, the colloid reactions, the Wassermann, flocculation and hemolysin reactions and the diagnostic and prognostic and therapeutic significance of lumbar puncture.

RECORD FORMS FOR SOCIAL WORKERS

A Form of Record for Hospital Social Work. Including suggestions on organization. By Gertrude L. Farmer, Director, Department of Social Work of the Boston City Hospital. Price $1.50. Philadelphia, London and Montreal: J. B. Lippincott Company, 1921.

The six chapters of this little manual of eighty-one pages are devoted to various record forms, the short service record, the five by eight record, the extension folder, further uses of the extension record system and illustrative records. While primarily intended for hospital extension work and for the benefit of the discharged patient the matter is naturally of interest to all social workers.

BEGINNER'S BOOK IN PSYCHOANALYSIS

Your Hidden Powers. By James Oppenheim. New York: Alfred A. Knopf, 1923.

Mr. Oppenheim complains of the lack of an adequate Beginner's Book in Psychoanalysis. He proposes to furnish one. And so he does. But one feels, after reading it, that the beginners are just about as far as they were before. He acquaints them with certain new words; he outlines the subject rather warily; he answers a number of the more usual lay questions. Then he moralizes. The book is really a collection of essays on lofty ideals and fine feelings. From time to time his poetry carries him away and he produces a really delicate piece of writing that delights the reader for apt expression of general ideas. He does emphasize the needs of the individual—self knowledge, and work. But he does not show clearly or unmistakably how these ends are to be attained. So the Beginner's Psychoanalysis still remains to be written. The columnar essayists have added another stick or so to their easily read, easily digested, world direction of thought!

A PSYCHOPATHIC STUDY OF EDGAR ALLEN POE

Edgar A. Poe. A Psychopathic Study. By John W. Robertson, M.D. New York and London: G. P. Putnam's Sons, 1923. Pp. 331.

The interest which the reading of this book arouses in the subject of the work, this man of brilliancy and of sorrows, one might consider as a tribute only to the memory of Poe. But it denotes that the author has accomplished the purpose of his work, evidently a labor of love. The book is one written under a deep appreciation of the character and work of Poe by one who is familiar with his material and has the background of the mental scientist able to weigh facts. He has cleared the field of longstanding calumnies against the character of Poe which the world had carelessly accepted without the effort of such scientific investigation. Robertson lays emphasis through his careful psychiatric examination of it upon the actual pathological basis of Poe's erratic life. He distinguishes between the illness which so often incapacitated him from work and the actual force of his genius, instead of blindly ascribing his brilliant productions to the disturbances of his power which arose. Though genius and mental disturbance may exist side by side the latter is not dependent on the former as is popularly supposed. The book, readable as it is, would gain in clearness by some condensation especially in the first part. There is often repetition. Furthermore, we would disagree with Robertson that psychology, especially its newer form, could not add still more understanding to the life and character of this remarkable man. The author's discussion of the significance of the brain tissue behind personalities has at times an ominously materialistic sound but his own practical psychological viewpoint fortunately outruns this narrower one.

◆

Medicoliterary Notes.

The forty-fifth annual report of the Department of Health of the State of New Jersey for 1922 has just been issued. The two functions especially emphasized are those of food, beverage, and water supply sanitation, and the compilation of complete and accurate vital statistics.

* * *

The Ethiopian Art Theater, a company of Negro actors, are presenting under the direction of Raymond O'Neil two interesting plays—*The Chip Woman's Fortune,* which might almost be called a folk drama, and which is excellently done, and Oscar Wilde's *Salome,* not so successful, partly because the play itself is essentially a drama for reading and not for acting.

* * *

The Philadelphia General Hospital has recently issued the tenth volume of its Reports, succeeding the volume issued in 1913. It is a valuable contribution to medical literature, consisting as it does of clinical papers most of which have not heretofore been published.

* * *

The Distinguished Service Medal has recently been awarded to Miss Adèle Poston, of this city, formerly superintendent of nurses at Bloomingdale Hospital. Miss Poston organized the first unit of psychiatric nurses sent abroad for treatment of mental and nervous conditions in the A. E. F., and acted as chief nurse of Base Hospital 117, the first American hospital for war neuroses.

* * *

Summer courses in psychiatric social work will be given in two graduate schools for social work—Smith College, and the New York School for Social Work. The eight weeks session of the Smith College school will open on June 5th, and the course at the New York school will begin on June 14th and continue until July 25th.

* * *

The Cancer Commission of Harvard University has recently issued the tenth annual report of the Collis P. Huntington Memorial Hospital and the Laboratories of the Commission, for the year ending June 30, 1922. The report states that the most notable event of the year's work was the completion of the new laboratory building and its designation by the president and fellows of Harvard College as the John Collins Warren Laboratory, "in grateful recognition of his valuable services to the University."

* * *

Public Health Reports for January 19th contains the address made by W. Mansfield Clark to the staff of the Hygienic Laboratory at the celebration of Pasteur's centenary. It is one of the best summaries of the work of the great French scientist that the many centenary celebrations brought forth.

* * *

One of the notable scientific contributions of the current year is the *Physiology of the Ascent of Sap,* by Sir Jagadis Chunder Bose, Director of Bose Research Institute, Calcutta, India. The book is published by Longmans, Green and Company. Doctor Bose's researches into this hitherto obscure and elusive problem in plant physiology have proved, he states, the existence of active pulsating cells in and throughout the plant from root to leaf whose pumping action gives rise to the conduction of the sap.

* * *

The *International Library of Psychology, Philosophy and Scientific Method,* published by Harcourt, Brace and Company, is soon to be enlarged by several new volumes. The late Dr. W. H. R. Rivers is the author of two volumes, *Psychology and Politics,* and *Conflict and Dream;* Prof. C. D. Broad's Scientific Thought reviews the progress in recent years of the concepts of time, space, motion, and matter; *The Meaning of Meanings,* by C. K. Ogden and I. A. Richards treats of the influence of symbolism and language upon present day thought; and—perhaps the most notable contribution for the physician—a translation of Dr. C. G. Jung's *Psychological Types,* with an introduction by Doctor Baynes.

* * *

Dr. Emile Weisweiller, chief of the Division of Venereal Diseases of the League of Red Cross Societies, has an interesting article in the *World's Health* for February on the foundation in Paris on January 27th of the *Union Internationale contre le Péril Vénérien.* The meeting was attended by representatives of British, French, Spanish, Swiss, and Belgian societies, by delegates of the League of Red Cross Societies, and unofficially by Japanese delegates. National societies of many other countries signified their allegiance in the union.

* * *

Sweden will be the first country in Europe to inaugurate a system of medical advice by radio from leading hospitals in the cities to Swedish ships at sea. Such a service is already in operation in this country.

* * *

C. A. Hoeffteke, of 7 Henley street, London, is about to bring out a book describing the extension method for treating various deformities and disabilities produced by disease and accident. The work should be a valuable source of information for medical men who are unacquainted with the remarkable results obtained by this method. The book will be published shortly by the medical department of William Heinemann, publishers, London.

Practical Therapeutics

NEW METHOD OF TOPICAL TREATMENT FOR GASTRODUODENAL DISEASES

By L. Winfield Kohn, M. D.,

New York.

With the hope of obtaining better results a few months ago I attempted to approach the treatment of gastroduodenal ulcer in a somewhat different manner from that ordinarily practised. Most of all was I convinced that ulcer of the stomach and duodenum, more especially the latter, was a common condition, despite the fact that the x ray was not always capable of exhibiting a definitely persistent pathognomonic defect or deformation. I also realized the unsuccessful results following the ordinary methods of medical treatment and the discouragement following surgery. To improve upon either of these methods was my aim. As a result, a combination of both was decided upon in the form of a mechanical and medical treatment. The results following this medicomechanical treatment have been most gratifying.

The treatment incorporates topical, medical and dietary considerations. Topical treatment, or the direct application of medical effort to gastroduodenal ulcer, can readily be appreciated. To render the ulcer accessible to direct treatment is one of the features of the method. Through the medium of the small fractional tube, this aim is readily realized. Forms of topical treatment of gastric ulcer have been resorted to in the past but not often nor in the manner advocated by this method.

Topical treatment of the past has lost vogue because success with it was not readily attained, because it was a too time consuming method, often distasteful to the patient, not persisted in by the physician, and because the larger tubes and improper medication only were mediums of choice. Today, however, with the small fractional tube at hand and valuable medicaments obtainable, we may aim at a more successful topical treatment. This must, however, be supported by proper medical and dietary indulgence.

When we consider the failures following pyloroplasty and gastrojejunostomy, the dangers associated with such destructive operations as pylorectomy, partial gastrectomy, resection, ulcer excision, etc., we readily appreciate the indications for medical treatment; yet, we must admit that there are times when operative measures cannot be dispensed with. One principle, however, that every medical man should subscribe to, is that of trying to reduce operative interference upon the gastrointestinal tract to a minimum. To my mind surgery should be resorted to only in acute conditions or in those instances where definite mechanical and troublesome complications have arisen.

If we hope to continue prescribing medical treatment for these many conditions, our effort will necessarily have to prove successful lest it may also be abandoned. The treatment in the past, which depended upon the principle of alkalinization through the taking of medicine alone per os and through regulated diet, has not always been sufficiently successful. To impose bed rest often proves exceedingly beneficial to the patient but a hardship because of economic conditions, and for that reason is not considered as frequently as it should be. Thus far, these different objections seem to have been satisfactorily overcome by the treatment to be described below. I, personally, regard it as the most satisfactory ambulatory method of treatment for gastroduodenal ulcer and other gastric conditions. Experience in the treatment of a large number of patients suffering from gastric ulcer, duodenal ulcer, gastritis, etc., has convinced me that a step in a progressive direction has been made. Amazing and most pleasing has been the relief experienced by many ambulatory patients through freedom from their subjective symptoms. In bed patients upon whom this treatment could be indulged more frequently and for more prolonged periods with better control, the result of treatment by this method should prove even more gratifying.

Before we dare hope to treat successfully ulcer or, for that matter, any organic disease of the stomach or duodenum, we must come to some definite conclusion as to the true nature of the existing condition. Then may we aim to approach the problem logically. Are we really dealing with ulcer? In just what portion of the stomach or duodenum is the ulcer located? Is the ulcer mucosal or deep? Has perforation ever occurred, and is the ulcer associated with troublesome adhesion formation? Has bleeding been prominently associated? Have we troublesome functional disturbances to contend with? Are there secondary intragastric developments of an organic nature, such as atony, muscle hypertrophy, scar tissue, and new growth? Is the ulcer acute or chronic, and are the adjacent tissues infiltrated? Often in duodenal ulcer the biliary tract gives evidence of being diseased, and unless this is taken into consideration the result of our treatment will be failure. The general constitutional condition of the patient must also be given our earnest concern, if we hope to be rewarded by definite improvement. It is no simple task to answer satisfactorily the aforementioned questions, but if we approach the problem in the manner implied by these queries, we are sure to better appreciate the necessities demanded.

After satisfying myself that the patient is suffering from ulcer, and after I have acquainted myself as thoroughly as possible with the associated local and general conditions that must not be overlooked, treatment is instituted. Practically every patient to whom I have given the treatment outlined below was ambulatory and all exhibited remarkable improvement both subjectively and objectively. Under objective improvement I would refer to disappearance of tenderness upon pressure rather than fluoroscopic improvement, though I have seen improvement fluoroscopically in relation to distributed peristalsis, motility and tone.

The plan of treatment instituted, whether the case was one of gastric or duodenal ulcer, was as follows: During the first week or ten days, depending upon the nature of the lesion as indicated by all of our studies, the patient was given a simple but restricted ulcer diet, which consisted of liquid foods every two hours, such as milk, albumen water, rice water, barley water, and cream. During the first week or longer the patient is instructed to return each morning with a practically empty stomach for topical treatment. In those patients who have shown pronounced subjective improvement, topical treatment may be given every other day, but to give daily treatment for a week or ten days is sure to bring great benefit to the patient. If the treatment is given gently and carefully, fifteen minutes to half an hour will necessarily elapse. First, simple lavage is instituted through a fractional tube. I have made use of a large three or four ounce Triumph syringe (glass) for instillation and aspiration purposes, also another more effective contrivance consisting of a four quart bottle with connections which through air pressure may fill the stomach and through vacuum creation may aspirate its contents. After the stomach has been thoroughly flushed with plain lukewarm water and emptied the next procedure is to instill a large quantity of weak sodium bicarbonate solution into the stomach. I made use of anywhere from 350 c.c. to 600 c.c., depending upon the patient's tolerance. About two tablespoonfuls or even less of bicarbonate of soda to a quart of water is used in making up the solution. This solution is allowed to remain in the stomach for a period of fifteen minutes or longer. We may, however, during this period withdraw a certain quantity and replace it with a similar amount, continuing the procedure throughout the entire period, in this way possibly getting rid of dissolved mucus.

Finally, the alkaline solution is removed and there is instilled into the stomach from one to three ounces of a colloidal silver solution of body temperature. This colloidal silver is of 0.05 per cent. strength and it can be diluted if desired. The silver solution is allowed to remain in the stomach and the tube is withdrawn. This concludes the topical treatment which may be given daily or less often as conditions may warrant. In those patients who have ulcer in the lowermost portion of the stomach or duodenum, the colloidal silver will of course have no difficulty in reaching the diseased area. In those individuals, however, who present evidences of ulcer higher up on the lesser curvature or at the cardiac end, it becomes necessary to give them this topical treatment while in the Trendelenberg position, and after the silver solution is applied the position should be maintained for at least fifteen minutes if possible. The Trendelenberg posture need not, however, be too extreme. This position enables the silver to gravitate toward the lesion and bathe it.

This treatment is given, if possible, once a day the first week, then when improvement is noted every second day the second week, and as subjective improvement continues is gradually cut down until finally the patient comes only once a week or even less often for it. It should, however, be given off and on for a few months. Simple increases in diet (bland foods) are ordered as improvement is noted. From the very beginning, it would seem wise to give antispasmodic treatment if indicated and also alkali treatment with such medication as sodium bicarbonate, bismuth or magnesium. The added medical treatment will, of course, depend upon the recognition of associated local or general disturbances. After the topical treatment has been reduced to once a week, it is usually my custom to prescribe this colloidal silver to be taken internally about twenty to thirty minutes after the alkaline powder is taken. I have always prescribed a mixture of powdered bismuth and soda three times a day one hour after each meal. The patient is instructed to take from one to two teaspoonfuls of the silver solution three times daily. This treatment is continued for weeks until definite improvement is admitted. There need be no fear of taking this particular colloidal silver internally. I have given it to large numbers of patients and have never noted any ill effects. The only objection at times is the manifestation of a metallic taste or momentary nausea.

The remarkable subjective and objective improvement obtained by this method of treatment cannot be overemphasized. The most intractable cases of ulcer, in which operations for relief had been performed, have been remarkably benefited by this treatment. In some cases it is necessary to indulge in topical treatment for a longer period of time than in others but one will be guided by the clinical progress noted. Sensible diet and adherence to the principle of alkalinization must be respected in practically every instance for a more or less lengthy period. I do not wish to subscribe myself to the belief that ulcers are permanently cured within a week or two by duodenal feeding and bed rest or any other method. I also believe that if we are to make headway in the direction of avoiding operative interference in cases of gastroduodenal ulcer, we will necessarily be forced to indulge in a direct treatment of the lesion. For that reason, I feel that topical treatment is a logical form of treatment.

SUMMARY.

The treatment comprises medical, dietary and topical application. 1. The medical treatment consists of the use of such medicaments per os daily as seem required, as, for instance, antispasmodics, alkalies, etc. 2. The diet should, of course, comprise such simple foods as are indicated only in conditions of gastroduodenal intolerance, such as milk, cream, water, egg albumen, etc., gradually working into the more complex articles of diet. 3. The topical treatment, the main feature of this method, consists of: a. simple lavage with lukewarm water so as to get rid of any accumulated or irritating material that may happen to be within the stomach; b. bathing with sodium bicarbonate solution for a period of ten to fifteen minutes or longer. This solution, because of its alkaline character, will neutralize the existing acidity and probably in this way through its thoroughness lessen the tendency that hyperacidity or hypersecretion may have of irritating the ulcer area. The osmotic nature of the solution may also exert a favorable influence in the direction of lessening hemorrhage as well as drying up the ulcer area. Mucus, which normally may be regarded as a protective secretion in the stomach, seems to act as a hindrance toward healing when medication is applied directly into the stomach, because it either combines with the medication introduced or because it interposes itself between the medication and the surface to be healed. By the use of this alkaline solution the mucus is well dissolved and after the stomach is cleansed the area to be treated should be rather accessible to the medicament to be instilled. A certain amount of this alkaline solution during its ten to fifteen minute exposure to the stomach, enters the duodenum in sufficient quantity to rid the duodenum of the presence of excess mucus, in this way preparing a duodenal ulcer for the medicament to be later introduced and left in the stomach.

c. The introduction into the stomach of from two to three ounces or more of a special colloidal silver solution (.05 per cent strength). This colloidal silver solution[1] is nontoxic, nonirritant and noncaustic. It is germicidal in its effect. This germicidal nature may be attributed to either the activity of the great number of colloidal particles, the power of adsorption that these particles may exhibit toward bacteria or other toxic substances present in the stomach or duodenum, the definite destructive influence that silver in such great surface exposure may have upon bacteria or toxins or the beneficial hearing that the silver colloid may have in improving the local or general resistance of the body against disease producing elements. At least, we may feel sure that this colloidal silver reduces the tendency toward infectivity to a minimum and in this way aids in a great measure the healing of ulcer processes. It is also very likely that the great surface exposure of the silver directly stimulates healing of the ulcer or improves the local tone of the tissues in this direction. The effect of the silver also is mildly astringent and the tissue seems to lose its vulnerability. It is not unlikely that this colloidal silver also tends to improve the local function of the organs to which it is applied and as a result may contribute in this way to ulcer healing. Whether this is brought about through the supposed beneficial influence that colloids are regarded to have upon the blood direct or upon the local nutrition is questionable. However, it is not my aim to touch upon the details of colloidal activity. My purpose is to present this article so that the excellent results obtained by this method might be made known.

Before concluding, I desire to mention the fact that we are also making use of colloidal iodine and other colloidal substances in the treatment of gastroduodenal ulcer and other diseases of the gastrointestinal tract. These substances are being employed not only locally but internally through mouth, intramuscular and intravenous means.

427 Park Avenue.

---

[1]The colloidal silver employed in my work is marketed under the name of collene.

Diagnosis and Treatment of Gallbladder Disease With Special Reference to the Meltzer-Lyon Test.—Walter C. Alvarez (*Medical Clinics of North America,* September, 1922) states that in making the diagnosis of gallbladder disease, a good history is essential. This should include the investigation of supposed attacks of ptomaine poisoning, cholecystitis and pains, beginning in the liver region and radiating to the back and right shoulder blade and aggravated by jolting; belching and bloating, socalled biliousness, nausea, regurgitation of food, heart burn and vomiting; the fear of the patient to eat even though the food bears no relationship to the attack is most characteristic. The history of typhoid fever, chronic sinusitis, empyema, or any prolonged infectious process is suggestive, as is also the presence of arthritis, myocarditis and certain forms of headache and dizziness. The physical examination reveals a tender edge of the liver, a positive Murphy maneuvre and also fibroids of the uterus and other pelvic abnormalities. Röntgenography aids by excluding organic lesions (ulcer and cancer of the stomach), by revealing calculi or a thickened gallbladder and cardiospasm; the stomach shows hypertonicity and overactivity, sometimes contraction of the pyloric antrum, gastric stasis, deformity of the duodenal cap, exaggerated colonic haustration and an enlarged liver. Gastric analysis shows achlorhydria.

The patient may die or recover without any treatment. Remissions are frequent. The diet should be smooth and poor in cellulose. Carlsbad salts are useful. Sodium bicarbonate may be used for heartburn and belching. Hoffman's anodyne helps considerably in the attacks occurring at night. Paregoric, morphine and papaverin may be given for paroxysmal pain. Medical treatment is indicated under the following conditions, 1, In the early stages of the disease, with mild symptoms and long intervals of relief and in a good general condition; 2, in patients with symptoms of cholecystitis, associated with nervousness, menopausal storms, hypertension, or myocarditis; 3, in the presence of complications; 4, in patients who suffer after a cholecystectomy. Surgical treatment is indicated in: 1, patients, in whom the attacks are getting worse and more often; 2, cases of severe indigestion; 3, cases relieved by drainage of the gallbladder, but in which there is a return of pain, probably due to the formation of new calculi. Any gallbladder, handicapped by stones or the scars of previous disease, should be extirpated. The Lyon technic cannot affect stones already present, but it is worth trying if surgical help is postponed or refused.

Treatment of Infectious Processes in the Abdominal Cavity.—Egon Ewald Pribram (*Zentralblatt für Gynäkologie,* November 25, 1922) asserts that the primary closure of the peritoneum should be practised more often than heretofore in localized infectious processes with slight exudate and still more in diffuse processes, because very often the peritoneum is well able to take care of the pus that forms subsequently. This procedure has very great advantages: aside from the shortening of the period of convalescence and the resulting diminution of postoperative thromboses, the dangers from extensive adhesions. If drainage is necessary, only rubber or glass tubes should be used, but never gauze.

Proceedings of Societies

AMERICAN GASTROENTEROLOGICAL ASSOCIATION

Twenty-fifth Annual Meeting, Held in Washington, D. C., May 1 and 2, 1922.

DR. ALLEN A. JONES, of Buffalo, N. Y., in the Chair.

Relation of Organic to Functional Intestinal Disease.—Dr. ALLEN A. JONES, of Buffalo, N. Y., read a paper on this subject as his presidential address.

Rôle of Spasticity in Diseases of the Digestive Tract.—Dr. JACOB KAUFMAN, of New York, reported an instructive case of this kind, in connection with which he discussed the question of whether spasticity was not more frequently a causative factor in the development of diseases of the digestive tract than was considered at present.

Sausage Skin as an Aid in X Ray Esophageal Diagnosis.—Dr. ARMISTED C. CRUMP, of New York, presented a paper on this subject, in which he stressed its ease of passage in late, as well as in early, esophageal involvement. He described a special esophageal bougie for use with the sausage skin, and its method of passage on a flexible tip piano wire, as a guide. The instrument gives an accurate measurement of the point of obstruction and extent of involvement. The shadow of the measurements appear on the same plate, in contrast to the bismuth shadow of the esophagus. It may be used as a record of improvement in cicatricial strictures. It gives a clearly defined limit of a neoplasm, which is important for radium treatment and for mapping out a surgical operation. The author exhibited lantern slides showing the normal esophagus, strictures due to acid or caustic soda, and diverticular neoplasms.

Clinical Importance of the Chronic Changes in the Appendix Which Are Discovered by the X Ray.—Dr. FRANKLIN W. WHITE, of Boston, first discussed the important direct signs, including tenderness, fixation, kinking, change of shape, and abnormal position. He then took up the question of the significance of the filling or nonfilling of the appendix, and its relation to the kind of barium meal used. Other points discussed were the time of emptying the appendix; the cause of beading, or segmentation; the limited value of indirect signs, such as pyloric spasm, gastric residue and ileal stasis.

Under the heading of the Clinical Importance of the Signs, Dr. White considered the question of whether there were any normal appendices in adults and whether obliteration was a normal or an abnormal process. He said that the x ray discovered many things about the appendix which might or might not trouble the patient; such as limited mobility, small fecal masses, peculiar shapes, obliteration of the lumen, beading, and moderate delay in emptying. Their discovery, he stated, was frequently no reason for removing the appendix. The most frequent signs in the group requiring operation, and the signs found in the operative group, were then considered. Dr. White illustrated by lantern slides a study of a series of patients from one to four years after an x ray examination that showed chronic changes in the appendix.

Peptic Ulcers With Deformities of the Viscus (as Indicated by the X Ray) Changed for the Better by Treatment.—Dr. MAX EINHORN, of New York, stated that twelve cases of peptic ulcers with deformities of the stomach, pylorus or duodenum (as evidenced by the x ray) had been observed in one year. There were among them five cases of penetrating ulcer of the lesser curvature of the stomach, one of penetrating ulcer near the pylorus, and six of duodenal ulcers with marked deformities of the first position of the duodenum. Duodenal elimination treatment effected a marked amelioration, if not a cure, in all of them. The deformities of the viscus had either disappeared entirely or had given place to a more normal appearance of the latter. The cases showed clearly that even old, far advanced, peptic ulcers were amenable to medical treatment.

Vails in the Right Hypochondrium.—Dr. LEWIS G. COLE, of New York, said that vails in the right hypochondrium involved the pars pylorica, cap, duodenum and colon, and extended from the hollow viscera to the gallbladder and liver. These vails may be either congenital or acquired; and when congenital, were due to abnormalities of the anterior mesogastrium, as was emphasized by Harris. When acquired, they were slight vailing, nonobstructive adhesions, usually of gallbladder origin, described by Morris as "cobwebs in the attic, of gallbladder origin" without a grossly diseased gallbladder and without gallstones. Dr. Cole considered these of röntgenological significance for two reasons: 1, because they might be mistaken for postpyloric ulcers, and, 2, because some were of clinical significance. The characteristic röntgen findings were referred to as having been published recently. The symptomatology was classified as far as possible, and the characteristic symptoms emphasized. The author said that the difficulties of detecting these vails and the likelihood of overlooking them at a surgical exploration, unless the surgeon was familiar with them, was very great. The failures and success of the surgical procedure in the relief of the symptoms was analyzed.

Studies on Colon Function.—Dr. MARTIN E. REHFUSS, of Philadelphia, had made a study of colon function by means of x ray examination. He described the use of the irrigation method of fractional interpretation of results, which had been used in a clinical study of several thousand cases. He dilated on important points in colon retention and the points to be observed in the study of chronic constipation.

Underlying Causes in the Pathology of the Colon.—Dr. JEROME LYNCH, of New York, stated that the nerve supply to the gastrointestinal canal was developed segmentally. Each zone, or segment, as had been shown by Keith, he said, had its own pacemaker and its own rhythmical contractions. Disturbances in any segment are reflected in the others, and will interfere with the normal propulsion of food along the alimentary canal. These interferences may be congenital deformities or acquired. The congenital deformities may not result in pathological changes until adult age is reached, or they may be precipitated by improper dietetic habits.

Some of the most prominent congenital defects were ileocecal insufficiency, nonfunction of the cecum, elbow deformity of the ascending colon, adhesions of the gallbladder to the transverse colon or septum, and overdevelopment of the sigmoid. The acquired deformities were those due to chronic appendix, pericolitis, colocystitis, and perisigmoiditis.

Treatment of Spastic Constipation.—Dr. Charles D. Aaron, of Detroit, in this paper, laid particular emphasis on physical and mental relaxation of the patients, diet, medication and local applications.

Pancreatic Carcinoma: A Clinical Review.—Dr. George B. Eusterman, of Rochester, Minn., enlarged on the difficulties attending the recognition of pancreatic disease, particularly in its incipiency, and said that the differential diagnosis must be made between this and intraabdominal conditions that might simulate pancreatic disturbance. He then gave a brief discussion of types of lesions of this organ and their comparative frequency. Modern aids to diagnosis, and their practical application, were then considered. The author gave a clinical summary of a series of cases of pancreatic cancer, with the report of a recent interesting case.

Some Observations on the Gastric Disturbances Which Occur in Old Age.—Dr. Julius Friedenwald, of Baltimore, read this paper, in which he considered indiscretions in diet, the influence of diseases of other organs beyond the stomach itself, infectious diseases, focal infections, degenerative changes, arteriosclerosis, syphilis, toxemia and disturbances of the nervous system. The gastric secretion and motility in old age, as compared with these same functions in young adults, were discussed. The following diseases, as they occurred in old age in a series of three hundred cases, were analyzed: ulcer, cancer, dilatation, ptosis, syphilis, secondary gastric affections and visceral arteriosclerosis.

Treatment of Carcinoma of the Esophagus.—Dr. Elmer B. Freeman, of Baltimore, described the methods employed in the diagnosis of carcinoma of the esophagus, and then referred to a simple method of esophagoscopy and to an easy method of removing esophageal contents. The endoscopic appearance of carcinoma was then described. The author called attention to the necessity of frequent esophagoscopic examinations while undergoing treatment.

Hydrogen Ion Concentration Method of Gastric Analysis.—Dr. John H. King, of Baltimore, considered this subject under the following headings: 1, A clinical consideration of acidity; 2, determination of acidity, first by the electrometric method and second by colorimetric method; 3, buffers and indicators; 4, the acidity of stomach contents, and the significance of pH values in gastric contents; 5, the colorimetric determination of free hydrochloric acid, with a description of the method; 6, combined acidity and buffer value; 7, acid deficit of gastric contents; 8, analysis of results in clinical cases, in cases showing free hydrochloric acid—buffer value, and in cases showing achylia gastrica—acid deficit and buffer value; 9, the clinical significance of acid deficit and buffer values of gastric contents.

Studies on Gastric Secretion.—Dr. A. H. Aaron, of Buffalo, N. Y., in this paper, discussed the clinical value of the single gastric analysis, based on the study of a series of normal and pathological cases.

Local Treatment of Gastric Irritation.—Dr. Charles G. Stockton, of Buffalo, presented a paper dealing with measures of local treatment for the relief of gastric distress, including pain and anorexia, resulting from gastritis, erosion, ulcer and irritability from other conditions.

Diagnosis of Acute Intestinal Obstruction.—Dr. A. McGlannan, of Baltimore, said that acute intestinal obstruction was the most fatal of acute abdominal crises. The mortality had not been greatly reduced by aseptic surgery. Improvement in the statistical record of any large series of cases was to be credited, he thought, to earlier operation, rather than to improved technic. The cure of the patient rested on recognition of the lesion in the early stage, with prompt operation. The diagnosis of the general condition was more important than the identification of the etiological variety. The differentiation of obstruction from other lesions having similar symptoms was considered, and the limitation of nonoperative procedures discussed.

Early Diagnosis of Carcinoma of the Upper Colon.—Dr. Milton M. Portis and Dr. Sidney A. Portis, of Chicago, presented a paper on this subject, in which they stated that carcinomata of the colon were not as rare as commonly supposed. They were most common in the sigmoid, but might be found anywhere. Adenocarcinomata were the most frequent, but scirrhous and colloid growths were found. Pain was the most important symptom. Gastrointestinal complaints, with loss of weight and anemia, were present. Constipation alternated with diarrhea. The stools showed gross blood in some of the cases, while occult blood was found in all. Occult blood was one of the early findings, and the one of greatest significance. X ray evidence of a filling defect was an important sign. Obstruction was noted in advanced cases. In the differential diagnosis, all chronic intestinal conditions must be excluded. The authors gave a report of four cases with early diagnosis and operation. Lantern slides were exhibited, showing x ray evidence of carcinomatous lesions.

Selection of Patients Giving Indication and Contraindications for the Use of Medical Drainage of the Gall Tract.—Dr. B. B. Vincent Lyon, of Philadelphia, stated that the first requisite was to learn the type of gallbladder disease which could be treated by nonsurgical biliary tract drainage, and those which could not and should not be so treated until after they had been referred for operation. In a general way, the majority of all cases, he said, could be divided into several groups, in so far as the beginnings of their treatment are concerned. These groups are as follows:

Group A.: Cases that imperatively required surgery and that had relatively unimportant or no surgical contraindications. Group B.: Those cases that might unquestionably be considered surgical, but in which there were such serious contraindications as not to justify the surgical and anesthetic risks, if nonsurgical drainage could be shown to be an adequate alternative method. Group C.: Borderline cases, formerly considered surgical, but which now might do as well or better by medical drainage of the gall tract. Group D.: Early cases, for which surgery was no longer indicated, since similar cases had made satisfactory recoveries by medical drainage. Group E.: Genuinely surgical cases, to be preceded by preliminary medical drainage. Group F.: Genuinely surgical cases, to be followed by medical drainage. Group G.: Essentially medical cases: 1, Catarrhal jaundice; 2, arthritis; 3, typhoid carriers.

Intestinal Infection With Entamœba Histolytica as a Factor in Arthritis Deformans.—Dr. Sidney K. Simon, of New Orleans, La., said that the finding of Entamœba histolytica in the periarticular tissues in two cases of arthritis deformans had been reported recently by Kofold. The suggestion had been made that this protozoal organism might be a causative factor in this, as well as in other types of chronic polyarthritis. The author reported a case in his experience presenting extensive arthritis changes. The presence of entamœbic infection of the intestinal tract in an active form had likewise been demonstrated in his patient.

Chemical Composition of Intestinal Toxines; Pharmacology Thereof, and Treatment of Intestinal Toxemia.—Dr. John C. Hemmeter, of Baltimore, Md., said that the chemical structure of p-hydroxyphenylethylamine is allied to that of the alkaloids of ergot and to adrenalin. He referred to the blood pressure raising effect, enterotoxins in diet, the effect on the differential blood count, intestinal bacteria, diet, and enterotoxin production. He then described the method of diagnosis by detection of para-hydroxyphenylacetic in the urine; the symptoms of hypertonicity of the sympathetic system, etc., and the biological test with the blood of the patient. The treatment consisted in restriction of diet, intestinal disinfection, the use of autogenous vaccines, lavage of the colon, etc.

The Diagnostic and Therapeutic Value of Transduodenalobiliary Drainage.—Dr. Elmer L. Eggleston, of Battle Creek, Mich., read this paper, in which he said that the evolution of new diagnostic methods or therapeutic methods should be welcomed by the profession. While they must be subjected to rigid inspection, they should not be condemned as worthless without an unprejudiced trial. The work of Doyon, Oddi and Meltzer, he said, formed the groundwork for a study of the bile derived apparently from different sources, and certainly revealed changes from the normal in its macroscopical and microscopical appearance, its chemical composition and its bacteriological and cytological findings. This should aid us in differentiating certain right upper quadrant lesions, at present difficult of diagnosis, and might lessen the necessity of resorting to so frequent surgical exploration to establish a positive diagnosis. The author said that their observations, covering a series of six hundred duodenobiliary drainages in three hundred cases, would warrant the belief that while it was helpful diagnostically, it did not take precedence over other procedures of proved value. Deductions from bacteriological findings were questionable, because of the great possibility of contamination from other sources. Bacteriological studies on bile removed from gallbladders immediately after operation frequently failed to corroborate preoperative drainage findings. The opportunity afforded for the study of the pancreatic ferments should aid materially in determining functional disturbances of that gland in a way superior to any yet advanced. The therapeutic value of the procedure was still undecided; in selected cases, it was apparently helpful. The author gave a brief review of such cases.

Visceral Adhesions and Bands; Normal Incidence in Relation to Age and Sex.—Dr. John Bryant, of Boston, Mass., stated that the existing data were contradictory and inadequate. He described the method of investigation, and gave his conclusions, based upon 1,131 observations upon 297 unselected conservative postmortem sections of all ages and both sexes. There was a surprising frequency of adhesions in the fetus of both sexes, but of a type very different from those found in the second half of life. The age of forty was found to be a critical one for both sexes, there being almost no increase in frequency above the fetal rate until this age. From forty years to old age, there was a marked increase in the complex type of adhesions, especially in the female. Findings were given for individual organs in both sexes with regard to age. Nearly all of the foregoing papers were fully discussed.

Letters to the Editor.

A NEW SIGN IN SUBACUTE AND CHRONIC APPENDICITIS

Los Angeles, Calif., *April* 19, 1923.

To the Editor:

During the past two years I have particularly noted that there could be elicited, very often, a tender point in the right tenth costal interspace in the axillary line or slightly posterior. This tender point is analogous to the reflex tender points elicited quite often posterior to the right or left of the spine in cases of gallstones (or gallbladder irritation) and gastric ulcer. Though not a great many cases have been seen, yet I feel that in these cases, about 110 to 120 in number, the sign has been present sufficiently frequent to warrant further study.

The investigation as to the sign in the acute cases has not been nearly so great, for the reason that the general practitioners refer their acute cases immediately to the surgeon for operation and this study was not readily available. In the limited few, this sign was often present. Many theories could be advanced for this sign but it is deemed advisable not to advance such until further studies are made.

Samuel Floersheim.

Abstracts from Current Literature

GASTROINTESTINAL DISEASES.

Atropine in the Treatment of Congenital Pyloric Stenosis.—Murray H. Bass (*Medical Clinics of North America,* November, 1922) reports his results in several cases of congenital pyloric stenosis with large doses of atropine. A freshly prepared solution of atropine from a reliable source is essential and the minimum dose should be allowed to become effective as rapidly as possible. It is well to begin with one drop of a one in one thousand solution of atropine sulphate in water, given with each feeding; if the vomiting is not controlled by it, an additional drop should be given at the following feeding. The author has given as high as seventy-two drops in twenty-four hours. In the severer cases atropine is given hypodermically. The amount of atropine necessary to control the vomiting varies in individual cases. The guide to tolerance of the drug is flushing of the skin. In patients who are recovering the atropine is gradually diminished rather than stopped suddenly. The atropine merely serves to remove the pyloric spasm and every other possible aid should be used to maintain the nutrition of the child. The best trained nursing is necessary in these cases. The best type of food is determined by the physician in every case individually. Gastric lavage before each feeding may be necessary or gavage may have to be applied. Sufficient fluids must be administered either by mouth, or subcutaneous injections of normal saline solution, or by the Murphy rectal drip. In very debilitated infants transfusion may be advisable. The general hygienic measures must also be looked after. Cases of true stenosis must be differentiated from those of severe spasm by the presence of a palpable tumor. Every case of congenital pyloric stenosis should be given the benefit of a thorough course of treatment with atropine before resorting to surgical intervention.

Actinomycosis of the Gastrointestinal Tract: A Report of Fourteen Cases.—James Chester Brogden (*Journal of Laboratory and Clinical Medicine,* December, 1922) studied fourteen cases of actinomycosis of the gastrointestinal tract which have occurred at the Mayo Clinic since 1909; the disease, therefore, is not such a rare one, thirteen of the fourteen cases having occurred during the last four years. The prognosis in such cases is unfavorable, the mortality being from sixty to seventy per cent. Brogden draws the following conclusions from his investigation: The acute form, usually beginning with a typical attack of acute appendicitis, is more common. There may be severe or several mild attacks; the chronic form is insidious in onset with very slight indefinite pain in the lower abdomen, or practically no pain, the mass being the first sign of the disease. The characteristic symptoms in both forms are marked loss of weight and strength, pronounced anemia, induration, and a bluish red discoloration of the skin over the mass and around the sinuses, and pain down the right thigh with flexion of the thigh on the abdomen. Constipation was the rule in the fourteen cases, diarrhea not being a constant symptom. Actinomycosis bovis, an anaerobic organism, is the cause of the disease; the ileocecal coil is most often affected; the stomach and upper small intestine being practically immune. Predisposing factors are carious teeth, diseased tonsils, bad hygienic conditions, etc.; whether the disease is transmitted from cattle to man is doubtful, though three of the fourteen cases gave a definite history of exposure to lumpy jaw in man. A chronic discharging sinus in the lower abdomen, particularly following operation and drainage of an appendiceal abscess, should arouse suspicion of actinomycosis, and repeated examinations for the ray fungi should be made, over long periods, with pathological examination of the tissue from the mass or from the walls of the sinuses, before actinomycosis can be ruled out. The best hope of cure is offered by early operation and excision of the diseased area before spread of the infection to the surrounding tissues, frequent röntgen ray and radium treatments over the abdomen and large doses of potassium iodide by mouth and sodium iodide intravenously. In the later stages radical surgical measures are of no help, death usually occurring from cachexia and extension of the disease to the liver and thorax.

Forty-four Cases of Simple Perforation of Gastric and Duodenal Ulcers, With a Simple Method of Surgical Treatment.—E. R. Schmidt (*Acta Chirurgica Scandinavica,* December 22, 1922) states in his résumé that the surgical condition of a patient is dependent upon two things, viz., his physical condition previous to the operation and the severity of the peritonitis after the perforation. If a patient is young, in good physical condition, has had an ulcer for some time so as to allow the abdomen to react by forming adhesions or developing a resistance, the patient will be able to combat a peritonitis of some duration. If the peritonitis is generalized, the young patient with a good constitution has a better prognosis than a patient young or old with a poor constitution. Time plays an important rôle. The greater the time elapsing between the operation and the perforation, the more marked is the peritonitis and the reaction on the system. The physical condition of the patient before perforation and operation and the severity of the peritonitis are the main factors upon which the mortality in any series will depend.

There are other factors, such as the tendencies to localize the peritonitis, the surgical procedure and complications (subphrenic abscess, pneumonia, emboli, empyema, thrombosis, bronchopneumonia) which play a less important rôle, but must be taken into consideration. In opening the abdomen, the high median incision was used in all cases. This incision immediately exposes the stomach and duodenum so that a minimum of handling is necessary. In treating the peritonitis in forty-two cases the abdomen was irrigated with normal saline solution at 40° C., and in two cases the localized area was sponged with sponges moistened in normal saline solution. Thirty-nine abdomens were closed without drainage, thus shortening the postoperative course, favoring early restoration of peristalsis and reducing the risk of postoperative ileus and the forming of adhesions. The average length of time the patients remained at the hospital was 33.39 days. There were ten cases of duodenal ulcer in the series, nine in males and one in a female. They were operated on an average of 10.75 hours after the perforation, with no deaths.

The author draws the following conclusions: 1. Perforation may occur at any age; but necessarily occurs more often during the ulcer bearing stage. 2. Mortality depends for the most part on three factors: the time elapsing between perforation and operation, the severity of the peritonitis, and the physical condition of the patient at the time of perforation. The mortality rates of the different series published will vary as these factors vary in the cases that comprise the series. 3. Gastroenterostomy is a superfluous procedure in the treatment of a perforated ulcer. By employing gastrostomy instead of gastroenterostomy the mortality rate can be reduced from two to 6.5 per cent. 4. Gastrostomy serves as a safety valve. Nourishment can be given through it even before the patient awakens from the narcosis. All the postoperative discomfort of eructations, hiccough, nausea and vomiting are eliminated. If lavage should be necessary, it is a simple procedure and not disagreeable to the patient. 5. Primary suture of the abdomen, after a thorough irrigation of the abdomen with normal salt solution at 40° C., makes for a smooth postoperative recovery. 6. Of twenty-two patients reexamined, only two had had to be reoperated upon for a recurrence of ulcer. 7. The patients on leaving the hospital must be forcibly impressed with the fact that an ulcer diet is essential for their continued freedom from a recurrence of the ulcer and they should remain under medical control for some time. 8. No cancer of the stomach developed in this series. 9. A high median line incision has proved most satisfactory. 10. Excision of the ulcer removes pathological tissue, allows approximation of the edges so that there is no protruding ulcerated surface on the inside, reduces the tension of the sutures, affords a better hold for the sutures and leaves less scar tissue after it is healed. 11. Ulcer patients should be warned of the possibility of recurrence of both ulcer and of perforation.

Chronic Digestive Insufficiency (Celiac Disease).—W. McKim Marriott (*Medical Clinics of North America,* July, 1922) states that the cardinal symptoms of celiac disease are emaciation, great fluctuation in the weight, protruding abdomen, large foul, soapy stools, and specific intolerance to fat in the food. It must be differentiated from abdominal tuberculosis, Hirschsprung's disease and emaciation from improper feeding, especially with a diet of much bulky food with little fat and protein. This disease is a purely functional digestive insufficiency.

The treatment includes a diet of sufficient calories, with protein and such forms of carbohydrates as do not readily ferment; it must not neutralize the slight amount of gastric hydrochloric acid; and it must also contain the three vitamines—fat soluble A, the water soluble B, and the antiscorbutic vitamines—and iron. The basis of the diet is skimmed lactic acid milk (buttermilk) in the amount of a quart a day; to this, curds from skimmed or a dried casein (larosan, casec, etc.) should be added. Codliver oil is given for the fat soluble A vitamine, one to two teaspoonfuls a day. For the water soluble B vitamine and iron, two to three teaspoonfuls of powdered spinach in a little water are added to the milk mixture. Orange juice (one tablespoonful) supplies the antiscorbutic vitamine. Additional protein is given in the form of rare, scraped beef or soft boiled egg. The starches include well cooked farina, cream of wheat, or baked potato. Additional calories are obtained with one half to three ounces of commercial dextrin or brown corn syrup. If necessary, five to ten c. c. of normal hydrochloric acid a day is added to the mixture before feedings for two or three days at a time only.

Lymphosarcoma of Intestine. — P. A. De Noyelles (*Annals of Surgery,* August, 1922) concludes as follows: two cases of lymphosarcoma of the intestine are described, one of tumor of the jejunum, the other of the ileum. In one instance the tumor was a diffuse infiltration of the intestinal wall, an annular type of growth. In the other case a lymphosarcomatous polyp was found which gave rise to an intussusception. The microscopic picture leaves much speculation as to the origin of the tumor cell, but in these two cases the predominant cell is one which resembles a great deal the transitional large mononuclear cell of the blood. Lymphosarcoma of the intestinal tract is difficult of clinical diagnosis, the signs being simply those of malignancy, with partial obstruction being rather constantly present. X ray examination was of no help in these two cases. Treatment consists of the radical removal of the primary growth with as much of the metastases as is possible. Improved methods of radium application might be a valuable therapeutic adjunct. Chronic irritation, possibly a specific toxin, may play an important rôle in the genesis of lymphosarcoma. The histology of infectious granulomata of the intestine often simulates this tumor. Perhaps lymphosarcoma is only one of the many bizarre late pictures of lesions which were at one time of the nature of Hodgkin's disease or lymphoblastic or lymphocytic aleucemia.

Angioma of Gastrointestinal Tract.—Judd and Rankin (*Annals of Surgery,* July, 1922) state that angiomas of the gastrointestinal tract are rare and may simulate malignant conditions. When they occur in the stomach, they are generally found on the posterior wall in the common location for malignant conditions. Similar to other benign tumors of the stomach, angiomas are occasionally found in young persons. There may be no definite gastric upset, the main complaint being weakness and epigastric discomfort. The acid values of the gastric secretion are generally normal and the general condition of the patient is usually much better than that of the patient with a similarly located malignant lesion. Angiomas of the stomach, while generally small, may grow to a large size. They are usually soft and covered with mucous membrane. Histologically, they are composed of fine bloodvessels and masses of fibroblasts and endothelial cells. At the Mayo Clinic three patients with angioma of the stomach and one with angioma of the duodenum have been operated on in the past two years; two of the patients were young, and two were of cancer age. The advanced age of these two patients and the x ray findings, similar to those in malignancy, suggested inoperable malignant lesions. In all cases the tumor was removed and operation was followed by an excellent immediate and late result.

The Gallbladder.—M. F. Porter (*Surgery, Gynecology, and Obstetrics,* July, 1922) asserts that routine removal of the gallbladder is based upon the following assumptions: 1. That the gallbladder is an unimportant organ and that its removal is followed by no untoward results. 2. That all gallstones have their origin in a primary cholecystitis and that recurrence or continuation of symptoms following cholecystostomy is usually due to the fact that the gallbladder was not removed. The facts are that all evidence at hand supports the contention that the gallbladder is an important organ and evidence is not yet at hand to warrant the conclusion that its removal leads to no serious consequences. Cholecystic disease including gallstones frequently if not usually originates in the liver. Routine cholecystectomy frequently fails to cure and leads to the removal of healthy gallbladders in over four per cent. of cases.

Relation of Achylia Gastrica to Chronic Focal Infections and Pernicious Anemia.—Louis A. Levison (*Journal of Laboratory and Clinical Medicine,* August, 1922) cites the history of three patients for the purpose of calling attention to the sequence of focal infection, achylia gastrica, and pernicious anemia. In his conclusions Levison states that the assumption is justifiable that long continued foci of infection may depress the gastric secretion and produce an achylia gastrica. However, that the latter condition in itself is a predisposing cause to pernicious anemia has not been shown on the basis of any evidence yet brought forward. Clinically there is reason to believe that focal infection of long duration may depress the function of the bone marrow and prevent the formation and development of new red blood cells. With these points in mind Levison urges that when achylia gastrica is discovered in a patient showing evidences of chronic focal infection, that the possibility of pernicious anemia developing be kept in mind, and that all possible efforts be made to eliminate the focal infection.

Epidemic Diarrhea. An Analysis of Eighty-four Fatal Cases.—Donald Paterson (*Lancet,* August 12, 1922) found: 1. That fatal cases of epidemic diarrhea fall into two groups—those with and those without a previous history of indigestion, the two types being indistinguishable clinically except for the history. 2. The involvement of the bowel was equal in frequency and extent in both groups. 3. The duration of the disease did not influence the extent of the pathological lesion in the bowel. 4. The most common lesion was a gross fatty change in the liver—an almost invariable finding in the previously healthy group. 5. The infectiousness of this disease was not strikingly apparent in the fatal cases. 6. The observation of Ballard—that the four foot earth temperature reaching 56° F. is synchronous with the outbreak of diarrhea—was borne out in 1921. 7. The feeding both during and after the acute symptoms is of the utmost importance and the original symptoms are reproduced when certain foods are given in some cases. 8. The administration of salines subcutaneously and intraperitoneally and fluids by mouth is essential to make up for the losses of fluid and dehydration; but only when the symptoms are urgent does the intraperitoneal method seem to be the best and it should be given at not more than 100° F., as it is not without danger.

The organisms most frequently isolated, in addition to the Bacillus coli communis, was the Bacillus coli anaerogenes; the other organisms were: Bacillus dysenteriæ, Bacillus paratyphosus B, and an unidentified bacillus. Morgan's No. 1 bacillus was not isolated in any case. The Bacillus coli anaerogenes may or may not have had an etiological significance and it was found in both the fatal and recovered cases; it also showed several strains.

Cancer of Bile Ducts.—K. Renshaw (*Annals of Surgery,* August, 1922) concludes as follows: Malignancy of the bile ducts, while less common than that of the gallbladder, is not uncommon. The ratio in a series of 104 cases of malignancy of the biliary ducts and gallbladder was one to four. Carcinoma is the most common type of neoplasm found. Gallstones would seem to be of greater etiological importance than is generally considered. Males and females are affected in the ratio of about two to one. About two thirds of the cases occur between the ages of fifty and seventy years. A diagnosis of malignancy of the ducts is uncertain. After a diagnosis of obstructive jaundice has been made, exploration is generally advisable. From the viewpoint of slowness of growth and rarity of metastasis, surgical treatment should be favorable.

Carcinoma of the Stomach.—F. N. G. Starr (*Canadian Medical Association Journal,* April, 1921) maintains that an inoperable primary carcinoma of the stomach may become operable following a simple palliative gastroenterostomy. In a locally inoperable carcinoma of the pylorus, with no metastases, an anterior gastroenterostomy is preferable to the posterior, in view of the possibility of a subsequent resection being possible. All palliative gastroenterostomies should be followed by x ray examination. In placing the anastomosis, following stomach resection, care should be taken to have the efflux leave the stomach and enter the jejunum at the lesser curvature, as this markedly decreases postoperative nausea. The hope of increased operability and prolongation of life lies in early diagnosis. This should mean that all patients suffering from chronic gastric distress, should be examined by means of x ray after an opaque meal. Serial plates should be made to avoid errors in diagnosis resulting from the use of a single plate. In addition, it is extremely important to have the plates interpreted by one who is thoroughly conversant with gastrointestinal roentgenology.

Chronic Duodenal Ileus.—D. P. D. Wilkie (*British Journal of Surgery,* October, 1921) concludes that chronic duodenal ileus from compression of the third part of the duodenum by the root of the mesentery is a clinical and pathological entity. It may be associated with duodenal or gastric ulcer, and with biliary and pancreatic lesions. Visceroptosis, and congenital lack of fixation of the proximal colon, predispose to its development. Fixation of the proximal colon may relieve certain cases. Drainage of the dilated duodenum by duodenojejunostomy is the most certain method of treatment, and the only one suited for well developed and late cases. Acute dilatation of the stomach, either idiopathic or postoperative, is probably merely a gross manifestation of a chronic condition which had been present previously.

Origin of Hunger Pains and Their Significance in the Diagnosis of Ulcer.—Heinrich Schur (*Wiener klinische Wochenschrift,* August 10, 1922) states that painful gastric ulcer is regularly associated with local inflammatory symptoms and swelling of the regional lymph nodes, to which the pains may be attributed. The pains are not caused by mechanical (food) or chemical (pepsin hydrochloric acid) irritation, but by the more or less inflamed ulcer area as a result of external pressure and contractions, which pull on the musculature surrounding the inflammatory foci. Hunger pains are absolute proof of an inflammation in the region of the pylorus; as a rule the lesion is an ulcer, but the diagnosis is made absolutely certain by the periodicity.

Chronic Gastritis.—Oskar Stoerk (*Wiener klinische Wochenschrift,* November 2, 1922) shows that the genetic pathological process responsible for chronic gastritis is a chemical inflammation resulting from disturbances of the protection against autodigestion of the stomach; if the intensity of this change is severe enough, healing does not occur, but instead there results the formation of a pathological form of mucous membrane—the socalled pseudopyloric mucosa—which, as a rule, seems to be capable of a return to normal and, moreover, seems to lead to a disappearance of glandular tissue after a certain time and thus to an atrophy of the gastric mucous membrane. The possibilities of spontaneous healing, as through therapeutic and dietetic influences, is only imaginable more in the sense of a prevention of further dissemination along the surface.

Effect of Duodenal Contents Upon Gastric Secretion.—In a preliminary report, F. Kauders and O. Porges (*Wiener klinische Wochenschrift,* October 26, 1922) state that acids coming from the duodenum diminish the secretion of the stomach, which finding may well be correlated with the physiology of the pyloric reflex; with this mechanism an excessive secretion of gastric juice may be regulated. The reverse is to be expected from alkalies—which clinical experience would suggest—namely, that after the administration of alkalies in excess during gastric digestion there soon appears a recurrence of free acid in the stomach. This finding was demonstrated repeatedly. The author's experiments lead him to believe that an inhibition emanating from the duodenum is unlikely and it is more likely that there is an excitation. The osmotic and chemical stimuli, such as hypertonic and medium strength sodium chloride solutions and even sugar solutions acting upon the duodenum, reduce the gastric secretion still more; in fat, the inhibitory effect of the fatty acids also come into play.

Amebic Liver Abscess. — Leonard Rogers (*Lancet,* March 25, 1922) concludes that the vast majority of cases of large amebic liver abscesses, in which no bacteria are demonstrable, can be easily cured by repeated aspirations, together with the all important administration of ipecacuanha and emetine, which destroy the specific amebæ. In this way the mortality is reduced to one fourth of that resulting from the usual open operation. In the few exceptional cases, which require incision, sterile siphon drainage should always be employed so as to avoid the fatal secondary bacterial infections common formerly after the open drainage operation.

The Cause of Certain Acute Symptoms Following Gastroenterostomy.—Russell L. Haden and Thomas G. Orr (*Bulletin of the Johns Hopkins Hospital,* January, 1923) report a study of three patients in whom rather severe symptoms occurred following gastroenterostomy. The patients emphasize the importance of an upper intestinal tract intoxication as the cause of certain postoperative reactions, which are attributed in these cases to a poison probably formed in the duodenum following the gastroenterostomy. The mechanical factor has not been determined, but it is probably an obstruction to the outflow of the duodenal contents. The patients showed a marked increase in the nonprotein nitrogenous bodies of the blood, in general proportional to the severity of the intoxication. The two cases on which chemical studies of the urine were made showed with no food intake an enormous excretion of nitrogen, and a very striking suppression of chlorides. One case showed a marked alkalosis, as evidenced by the very high CO_2 combining power of the blood plasma.

Therapeutic Value of Vomiting in Intestinal Obstruction and Acute Appendicitis.—Sir Charters Symonds (*Practitioner,* March, 1923) maintains that the free administration of fluids, principally water, in suspected intestinal obstruction or acute appendicitis, is sound practice. After operation vomiting should be encouraged, especially in advanced cases, until the rejected material is free from bile. When hiccough is present and vomiting does not follow the free exhibition of fluids, the stomach should be washed out, in severe cases every four hours, in others two or three times a day. The injured bowel will maintain obstruction for two to four days, and during this period our best treatment is to encourage vomiting. To permit the reflexes to come into operation as soon as possible the preoperative dose of morphine should be omitted, the operation should be as brief as possible, the minimum amount of anesthetic should be employed, and morphine should be withheld until the rejected material is free from bile. When free vomiting has occurred the symptoms of toxemia are absent, and the prospects of recovery after operation are increased.

Factors in Dyspepsia.—Francis W. Palfrey (*Boston Medical and Surgical Journal,* October 12, 1922) says that most chronically disordered stomachs can still receive without symptoms most of the articles of a normal diet if only these are taken with thorough mastication in sufficiently small amounts. Patients in managing their own diets commonly have their attention too much fixed upon what they can eat, and pay too little attention to the amounts. Most dyspeptic patients are impatient and meddlesome with their stomachs, rather than gentle and systematic, and so become confused and discouraged. Osler mentions three and one quarter ounces of meat, two medium slices of stale bread, and one ounce of butter three times a day as a useful diet in hyperacidity. Smaller amounts of the same foods can be taken by most dyspeptic patients, and it often serves as an encouraging introduction to treatment to show the patient that he can take even small amounts of these substantial foods which he may formerly have feared, giving him reason to hope that he may gradually resume a normal diet.

Intestinal Protozoa.—Marshall C. Cheney (*Medical Clinics of North America,* September, 1922) emphasizes the importance of routine examinations of the stool in protozoal conditions of the intestine. A portion equal in volume to a walnut is sufficient and it should be taken from the softest portion of the stool, placed in an airtight container and sent immediately to the laboratory to be examined immediately; it is still more desirable to have the specimen collected in the laboratory to allow an earlier examination. The following points should be investigated: 1, the gross appearance—as to color, mucus, blood or pus; 2, the examination of wet smears for excess food, amebæ, flagellates, ova, pus, blood, balantidium and spirochetes; 3, the same examination after the addition of five per cent. potassium iodide in salt solution, saturated with iodine for starch residue and also to bring out the characteristics of cysts; 4, the benzidin test for occult blood. If the occasion demands it, the following procedures may be added: 5, the iron hematoxylin stain for the identification of parasites; 6, the brine loop concentration test for ova (Kofoid); 7, the gram stain of flora; and 8, cultures for the typhoid dysentery, or other groups, or for yeasts and molds.

The Pelvic Appendix.—Rutherford Morison (*Lancet,* September 9, 1922) concludes that inflammation of the appendix may mislead the expert diagnostician, as early abdominal pain and fever may both be absent. Not until perforation has occurred, generally at the distal end, are urgent symptoms noted. This is due to the fact that tension is not present, because this type of appendix can empty itself and the first serious pain results from perforation. Frequency of micturition, especially in boys, and retention of urine (rarely) are early symptoms. Careful rectal examination and a blood count may aid in establishing the diagnosis. A pelvic abscess may result from the localization of a diffuse peritoneal infection, from a leaking appendiceal abscess in the right iliac fossa, or from a leaking pelvic appendix. Rectal tenesmus is the most suggestive symptom of a pelvic abscess. The treatment of an inflamed pelvic appendix is early extirpation, except after the second day following a perforation and in the conditions of intestinal distention or acute illness, in which cases medical treatment is indicated until the abscess points appreciably in the rectum, so that it can be opened there. Intestinal obstruction frequently follows operations for pelvic appendicitis. Early operation is indicated and delay is fatal. A complicated fecal fistula may threaten life. In women, vaginal hysterectomy will save the majority of these patients.

Resection of the Stomach for Perforated Ulcer.—D. Eberle (*Schweizerische Medizinische Wochenschrift,* July 20, 1922) adds another successful case of gastrectomy to the fifty cases previously reported. The mortality in these cases is strikingly low, but nevertheless this operation is not as popular as it ought to be. Most surgeons consider this operation as indicated only in suitable cases—in the early stage of peritonitis when patient is in good condition and in the presence of simple topographical anatomical relationships. A more careful limitation for this operation would be to confine this operation to the cases in which the site of the perforation cannot be properly closed by suture. Extensive operative intervention must not be feared in these cases. The earlier the operation, the better the result, and the fate of the patient depends not so much upon the surgical technic as upon an early diagnosis by the physician.

Dyspepsia.—Horace W. Soper (*The Medical Clinics of North America,* July, 1922) applies the generic term dyspepsia to the group of symptoms produced by inhibiting agents, excluding gastric and duodenal ulcer, carcinoma and other new growths and also inflammatory processes and primary secretory disturbances. Clinically, the dyspepsia syndrome may be produced by a large number of etiologic factors, no matter what the cause. The diagnosis of dyspepsia is difficult and must be established by a process of exclusion and a very complete examination. The usual symptoms of dyspepsia are pressure, anorexia, distention, belching of gas, eructation of food, nausea, vomiting, or a capricious appetite. The various types of dyspepsia are the following: nervous, atonic, psychic, vagotonic, gallbladder, appendiceal and constipation dyspepsias. Organic disease in a nervous dyspeptic clouds the clinical picture.

Cascade Stomach.—J. H. Douglas Webster (*Lancet,* September 30, 1922) states that the subject of cascade or cup-and-spill stomach requires further observation before organic or spasmodic types can be definitely differentiated. It has been seen to occur in, 1, local ulcers or adhesions at the lesser curvature; 2, with pyloric and duodenal ulcers; 3, in normal stomachs; 4, with extreme meteorism, especially with distention of the splenic colon by gas; and 5, with extraventricular tumors.

Intestinal Antisepsis.—Lester R. Dragstedt, Carl A. Dragstedt, and Oliver M. Nisbet (*Journal of Laboratory and Clinical Medicine,* December, 1922) report that the direct application of antiseptic solutions to short segments of the intestine in animals does not effect sterilization or inhibit the production of intestinal poisons.

The Immunological Classification of Common Hay Fever Plants and Trees

By WILLIAM SCHEPPEGRELL, A.M., M.D.,
New Orleans,
President American Hay Fever Prevention Association; Ex-President American Academy of Ophthalmology and Otolaryngology; Chief Surgeon of Hay Fever Clinic, Charity Hospital,

GENERAL CONSIDERATION.

In the classification of plants in their relation to hay fever, the first distinction, to which we first called attention in 1909 (1), is a general one, viz., 1, wind pollinated, and, 2, not wind pollinated. As the pollen of plants that are not wind pollinated, even if active, can cause a reaction only on direct inhalation, the former only need be considered in hay fever. Omitting the group comprising the grasses, we eliminate the large majority of plants and trees from etiological relation to hay fever.

While there are many wind pollinated plants, which, by reason of the negative reaction of the pollen or of their scarcity, are harmless in hay fever, the variety of plants that may cause hay fever is nevertheless exceedingly large (2). Of the wormwoods, for instance, the most common hay fever plants in the Pacific and Rocky Mountain States, there are about two hundred varieties of ragweed and as many of the marsh elders and cockleburs, while of the grasses, there are several thousand varieties.

If the application of pollen therapy required the use of the extract of the same pollen to which the patient is sensitive, it would clearly make this method impracticable, especially as most patients react to many different pollens. We have conducted a careful series of investigations with a view of segregating all the most common hay fever pollens into groups which should be morphologically alike, and the number of which should be as few as possible in order to simplify the question of pollen therapy.

OBJECT OF CLASSIFICATION.

As the special object of this classification of hay fever pollens is to simplify immunological methods, the segregation of different pollens need not be limited by botanical boundaries, but should depend upon biological tests and clinical data. We have already noted (3) that in cases of fall hay fever the earlier forms frequently develop, showing that sensitization to one group of pollens tends to lower the resistance to other groups of pollens. Conversely we have also found that immunization to one group of pollens raised the patient's resistance to the pollens of the remaining group, proving that nonspecific protein therapy, by stimulating the defensive powers of the organism, also cooperates in developing this form of immunity.

The lack of absolute specificity in the majority of hay fever cases is clearly demonstrated by the analysis of one thousand cases in our hay fever clinic and private practice. All but three and a half per cent. of these cases, that were found positive to the grass, chenopod or ragweed group, showed a well defined reaction to at least one other of the remaining major groups, even although not sufficiently marked to have caused hay fever.

BASIS OF CLASSIFICATION.

The most clearly defined classification is that of the grasses, the principal cause of vernal-estival hay fever. As several hundred species of these may be found in one district, and fifteen or twenty of them blooming at the same time, it would be a hopeless task to immunize a patient to each of the species that he might inhale. As the result of a prolonged series of tests, including over one hundred varieties of grass pollens, we have been enabled to determine that all the grasses have a similar hay fever reaction. This similarity differs in degree, but in no case have we found a subject sensitive to one of the grass pollen, who did not to a more or less extent react to other grass pollen with which he was tested. These tests were made by the intradermal method, as the uncertainty of the absorption by the cutaneous method makes the result less dependable.

SELECTION OF MEMBERS OF GROUPS.

While the grouping of hay fever pollens from a biological viewpoint has proved of great advan-

Copyright, 1923, by A. R. Elliott Publishing Company.

tage in simplifying the diagnostic tests and treatment of hay fever, our experience has demonstrated that the most common member in the patient's vicinity of the group to which he reacts, should be selected for his immunization. If the tests with the timothy pollen extract, for instance, indicates that he is sensitive to the grasses, and the Johnson grass is the most common variety that reaches the pollinating stage in his neighborhood, this should be given the preference in his treatment.

When this is used, however, it will rarely be required to administer extracts of other members of the Gramineæ group, as the successful immunization with the Johnson grass pollen will protect the patient from the remaining grass pollens.

The same principle applies to the other groups. In many of the Eastern and Southern States, for instance, the giant ragweed is a more or less important factor in the autumnal hay fever, but our successful results in these cases have been derived from the administration of the common ragweed pollen extract only (4). For experimental purposes, we sometimes substitute the pollen extract of the giant ragweed in these cases, but without apparent charge in the effects of the treatment.

MAJOR GROUPS.

As the result of biological tests of over four hundred varieties of pollen, we have succeeded thus far in segregating the most important of these, both morphologically and botanically, into three major groups, as follows:

I. Ambrosiaceæ, or ragweed group. The principal cause of summer fall hay fever east of Kansas.

II. Artemisia or wormwood group. The principal cause of summer fall hay fever in the Pacific and Rocky Mountain States.

III. Gramineæ or grass group. The common cause of spring summer hay fever in the United States, Canada and Europe.

In addition to these, we have also segregated a list of minor groups which, while important in the aggregate, are individually less common, most of them being only of local interest. As a rule they demand attention more as complicating factors in patients subject to hay fever of the major groups than as individual causes of hay fever.

I. THE AMBROSIACEÆ OR RAGWEED GROUP.

The ragweed group is the most important in the United States, not only because the pollens of two members of the groups, the common ragweed and the giant ragweed, are the principal cause of fall hay fever in the States east of Kansas, but also because other members of this group are important factors in hay fever in most of the remaining States. This group is divided botanically, as well as morphologically, into the the following divisions (genera): 1, Ambrosia; 2, Gæmeria, and 3, Iva and Xanthium.

1. *Ambrosia, or Ragweed.*—This division contains about fifteen species, mostly native of America. The four following are of special importance in hay fever:

a. Ambrosia elatior, common ragweed (Fig. 1). This is the most ubiquitous and important of this division. It is an annual with spikes of green flowers (staminate) at the end of the branches, and pistillate or fertile flowers at the intersection of the branches with the stalks. It is a native of America and is found in dry soil from Nova Scotia to Florida and west to British Columbia and Mexico. It is comparatively rarer and local west of Kansas, and is there replaced by the western ragweed, the sandbur and the marsh elder, all of which also have abundant wind borne pollens. It has a spiculated pollen (Fig. 7), fifteen microns in diameter.

b. Ambrosia trifida, giant ragweed (Fig. 4). This replaces the common ragweed in moist soil in the Eastern, Middle and Southern States, and extends even as far west as Nebraska, Colorado and New Mexico. It frequently grows from ten to fifteen feet in height, permitting its pollen, which forms at the head, to be distributed over an extensive area. It blooms from August to October. The pollen resembles that of the common ragweed, both in appearance and reaction, but is larger (twenty microns).

c. Ambrosia psilostachya, western ragweed. This week is not as common in cities and towns as the common and giant ragweeds, have a preference for prairies and plains. It is, therefore, less important from a public health viewpoint, as it is less likely to reach the human nostrils. While not as abundant as the common and giant ragweeds, it has an extensive distribution, being found in moist open soil from Illinois and Wisconsin to the Saskatchewan, and westward and southwestward. It is a perennial, blooming from July to October. The pollen resembles that of the common ragweed, but is larger (twenty-five microns).

d. Ambrosia bidentata, lanceleaved ragweed. This is an annual found on prairies from Illinois to Missouri, Kansas, Louisiana and Texas. Like the western ragweed, it is uncommon in cities and towns. Its period of bloom is from July to September.

The four species of the Ambrosia division are almost synchronous in their pollinating season, which is from July to October, these limits varying somewhat according to the geographical location and weather conditions. Their pollens are all spiculated, and vary in size from fifteen to twenty-five microns. They give the same reaction to the lugol solution, which we use for staining our exposed atmospheric pollen plates. Based on several hundred tests, they all give similar reactions in subjects sensitive to any one of the pollens of this group.

Our general rule is to advise, for immunizing purposes, the member of the group that is most common in the locality of the patient. The great similarity of the reaction of these four species, however, is so marked, that we use the extracts from the common or giant ragweed for all cases of this group, especially as the western and lanceleaf ragweeds are infrequent near cities, and therefore less important factors in hay fever.

2. *Iva, Marsh Elder.*—These are herbaceous or shrubby, coarse plants with thick opposite leaves, and small nodding greenish white heads of flowers. There are about fifteen species in America, the five following being the more important factors in hay fever:

a. Iva axillaris, poverty weed. A perennial growing in saline or alkaline soil from Manitoba and

North Dakota to Western Nebraska, New Mexico, British Columbia and California. The pollen, spherical and twenty microns in diameter, is very abundant, and the plant is an important factor in localities where it is common. Its period of bloom is from May to September.

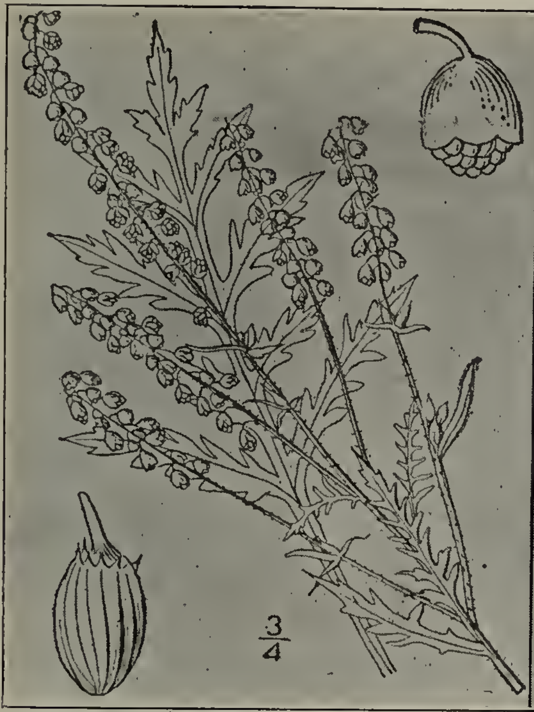

Fig. 1.

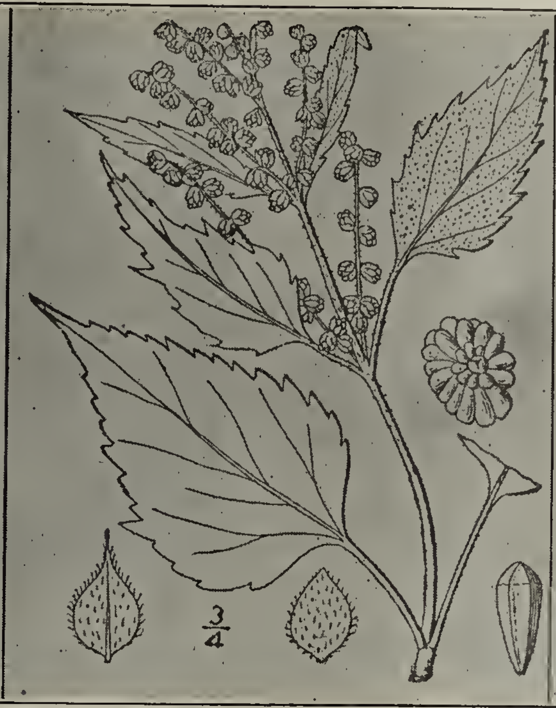

Fig. 2.

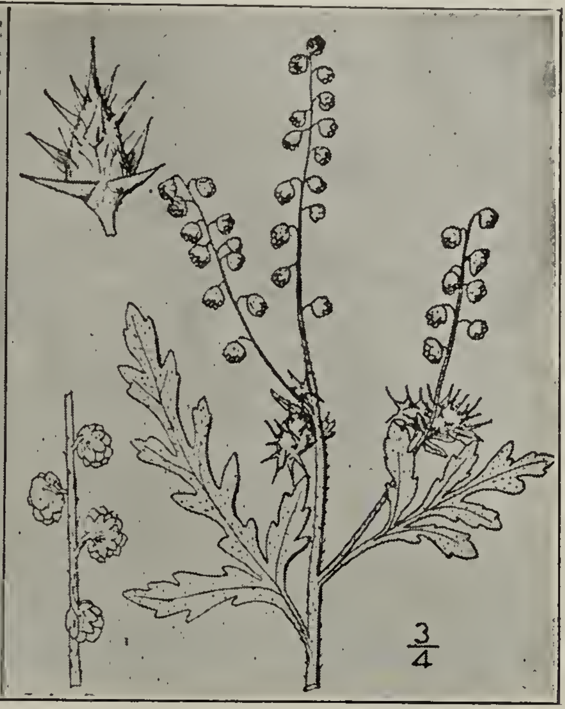

Fig. 3.

Fig. 1. Ambrosia elatior, common ragweed. Principal cause of autumnal hay fever west of Kansas.
Fig. 2. Iva xanthiifolia, great ragweed. Important member of the Ambrosiaceæ group west of Kansas.
Fig. 3. Gætneria acanthicarpa, false ragweed. Member of the Ambrosiaceæ group, common in some of the Western States.

b. Iva xanthifolia, burweed marsh elder (Fig. 2). This plant resembles the chenopods more than the ragweeds. It is an annual, growing in moist soil from Ontario to Wisconsin, Nebraska, New Mexico and Utah. It is sometimes found in waste places, but is most common near towns and cities. The pollen is ovoid, fifteen by twenty microns in diameter, and like all the other members of this group, is spiculated. It blooms from August to October.[1]

c. Iva ciliata, rough marsh elder. The abundant spiculated pollen, twenty-five microns in diameter, is distributed from August to November. It is an annual, growing in moist soil from Illinois to Nebraska, and south as far as Louisiana, Texas and Mexico. In some localities, as in the northeastern part of Louisiana, it is even more important in hay fever than the common and giant ragweeds.

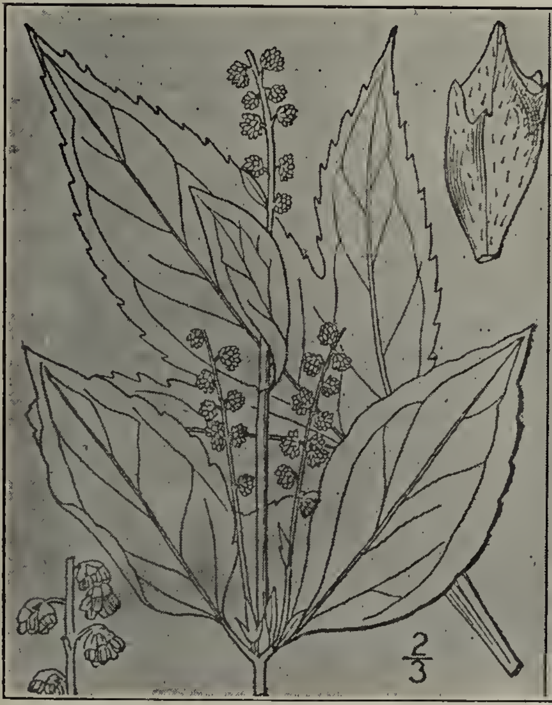

Fig. 4.

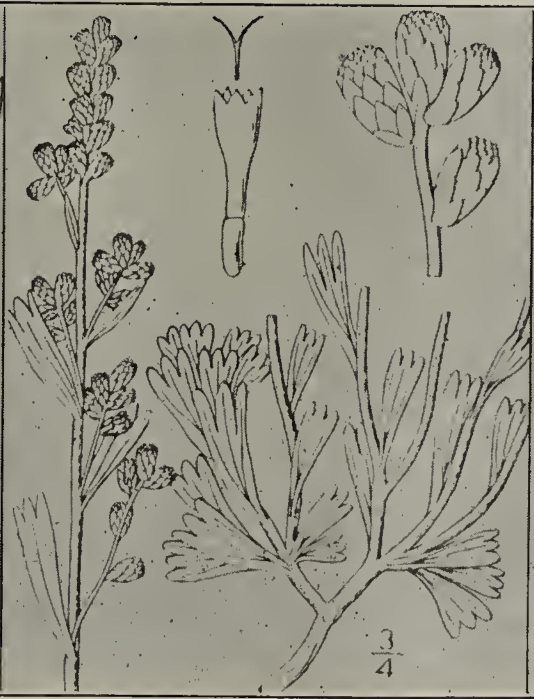

Fig. 5.

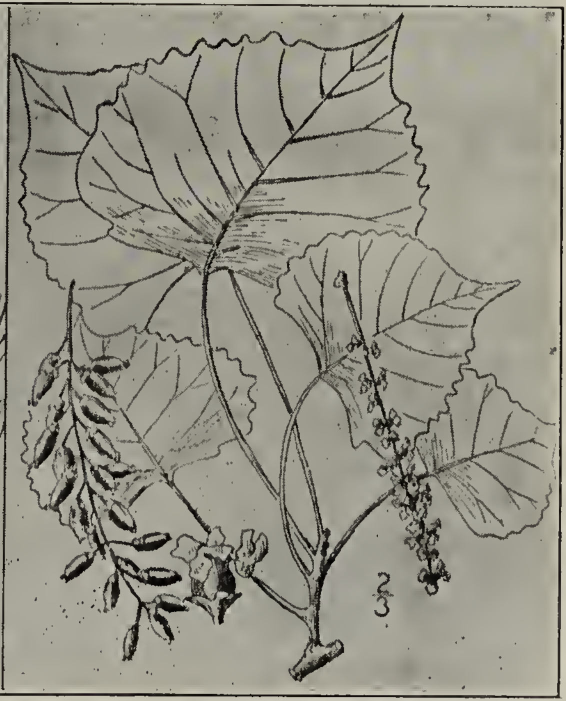

Fig. 6.

Fig. 4. Ambrosia trifida, giant ragweed. Important cause of autumnal hay fever in moist localities.
Fig. 5. Artemisia tridentata, sagebrush. The Artemisias form the principal cause of summer fall hay fever in the Pacific and Rocky Mountain States.
Fig. 6. Populus sargentii, cottonweed. Important local cause of early hay fever.

d. Iva frutescens, high water shrub. A perennial growing along salt marshes, and on muddy seashores, from Massachusetts to Florida and Texas, and blooming from July to September. On account of its habitat, it was formerly supposed to be a negligible member of this division, but we have found it to be a common cause of summer hay fever in subjects sensitive to the pollen of the ragweed group, when traveling on trains passing along marches and near the seashores where this weed is found.

---

[1] The line drawings of plants are from the work of Britton & Brown, *Illustrated Flora of the United States, Canada and the British Possessions.* (The photomicrographs are original.

3. *Gætneria or Franseria.*—Herbs or shrubs with the general appearance of the ragweeds, blooming in late summer and autumn. There are about twenty-five species, natives of America, the following being the more important in hay fever: Gætneria tenuifolia and Gætneria bipinnatifida.

With the exception of Gætneria tenuifolia, which extends eastward as far as Kansas, they are uncommon in the Eastern States, but are important factors in hay fever in many parts of the Pacific and Rocky Mountain States. The Gætneria acanthicarpa, or false ragweed (Fig. 3), is one of the most common weeds in New Mexico, and its pollen is a fruitful source of hay fever in that State.

4. *Xanthium, cocklebur.*—Coarse annuals, with fifteen species of wide geographical distribution, the most important in hay fever being the following:

a. Xanthium spinosum. Spiny or thorny cocklebur or clotbur. It is found in waste ground from Maine to Ontario, Florida, Illinois, West Virginia, Missouri, Texas, New Mexico and California. It blooms from August to November. This was originally naturalized from Europe or Asia, but, on account of its predilection for waste ground near cities and its wide geographical distribution, has become the most serious menace to hay fever of the Xanthium division of the Ambrosiaceæ group.

b. Xanthium americanum. American cocklebur or burweed. This blooms from June to November, and is found in moist soil from Ontario to Florida, Michigan, Tennessee and Kansas.

c. Xanthium canadense, Canadian clotbur. It blooms from August to October, and is found in moist soil from Quebec to Minnesota, New York, Missouri and Colorado.

While the species of the subdivisions of the Ambrosiaceæ groups bear a close resemblance in their biological reactions to one another, the subdivisions themselves are not so closely related. For immunizing purposes, however, while selecting the member of the group that is the most common in the patient's vicinity, we have rarely found it necessary to protect the patient against other members of the group after immunizing him against the dominant species.

II. THE ARTEMISIA OR WORMWOOD GROUP.

The Artemisias or wormwoods, by reason of their wide distribution, numerous species, ability to thrive under conditions unsuited to the majority of other plants, and the lightness and activity of their pollen, form the most important hay fever group of the Pacific and Rocky Mountain States. They are herbs or shrubby plants, bitter and aromatic, with small nodding heads in panicled spikes or racemes. Their pollens are trilobed (Fig. 8), and are stained brown by the lugol solution. There are about sixty-five species found in the western part of North America, twenty-five of which are fairly common, and most of them blooming between July and October. The more important species in hay fever are the following:

1. *Artemisia heterophylla or vulgaris, California mugwort.*—It is the most common cause of fall hay fever in California, and in other sections where it is abundant. It is found from California to British Columbia to Nevada, and more scattered as far east as Pennsylvania. It blooms from July to October.

2. *Artemisia tridentata, sagebrush.*—(Fig. 5). This is one of the most abundant shrubs from Western Nebraska to Colorado, Utah and California and north of Montana and British Columbia. The pollen is produced from August to November.

3. *Artemisia frigida, pasture sagebrush.*—A perennial blooming from July to October, and growing on dry plains and in rocky soil from Minnesota to Saskatchewan, Idaho, Nebraska, Texas and Arizona. It is found at levels as high as 5,000 feet, and is one of the few plants which may cause hay fever at such high altitudes.

III. THE GRAMINEÆ OR GRASS GROUP.

The grasses are responsible for the spring summer form of hay fever commonly called rose cold. Unlike the Ambrosiaceæ and Artemisia groups, which are confined to certain sections of the United States, the grasses are general in their geographical distribution, growing in all kinds of soil, and even in water. While hay fever due to ragweeds and wormweeds is unknown in Europe, hay fever from the grasses is of common occurrence.

The grasses form a large and important botanical group, and include those yielding food grains called cereals. There are about 4,500 species, widely distributed throughout the world. They should be distinguished from the allied rush (Juncaceæ) and sedge (Cyperaceæ) families, which by reason of the density of the outer coat (extine) of their pollen, are harmless in hay fever.

The number of hay fever cases due to the grasses is less than that caused by the ragweeds. The reason for this is that the pollen of the grasses (Fig. 9) are much less buoyant than those of the ragweeds, the former measuring from forty to fifty microns in diameter, while the common ragweed pollen is only fifteen microns, its potential area being still further increased by its spicules, which increase its buoyancy. In the case of the cereals, the pollens are especially large as, for instance, corn eighty microns, wheat fifty microns, and rye forty-five microns, so that they are responsible for hay fever only within limited areas.

While the similarity of the biological reaction of the grass pollens simplifies the diagnostic test and immunizing treatment, the extract to be used should preferably be prepared from the pollen that is most common in the patient's locality. This will usually give the most decided reaction in the test, and the best results in the treatment. The use of other grass pollen extracts will not be needed, however, inasmuch as the successful immunization with the extract of the principal grass pollen will protect the patient against the effects of other pollens of this group.

MINOR GROUPS.

While the pollens of the three major groups are responsible for the greater number of hay fever cases, the pollens of the minor groups cause a certain percentage of cases either directly, or more commonly, as secondary or complicating causes. To give a botanical list of all wind pollinated plants would simply complicate the subject, especially as a large proportion of these are not found within their potential area of municipalities, or in such small numbers that their pollens are negligible in hay fever.

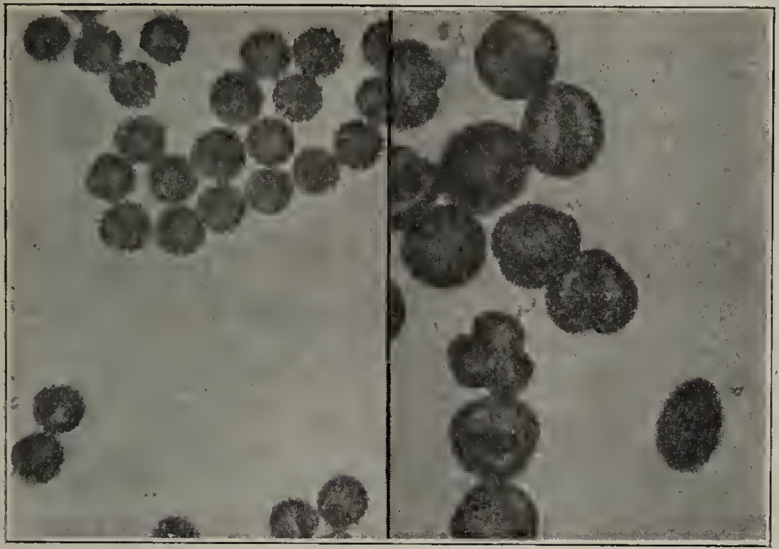

Fig. 7. Fig. 8.

Fig. 7. Pollen of common ragweed. Ambrosia elator.

Fig. 8. Pollen of California mugwort. Artemisia heterophylla.

The principal minor groups to be considered in hay fever are the following:

I. Chenopodiaceæ, goosefoot family.
II. Rumex, buckweed family.
III. Amaranthaceæ, amaranth family.
IV. Plantanaceæ, plantain family.
V. Trees.

In the segregation of these groups of hay fever pollens, the object is to simplify the subject so as to encourage and simplify immunological methods. Naturally there are plants in special localities which are not included in these groups; these are relatively few, however, but should not be overlooked by the earnest student of immunology .

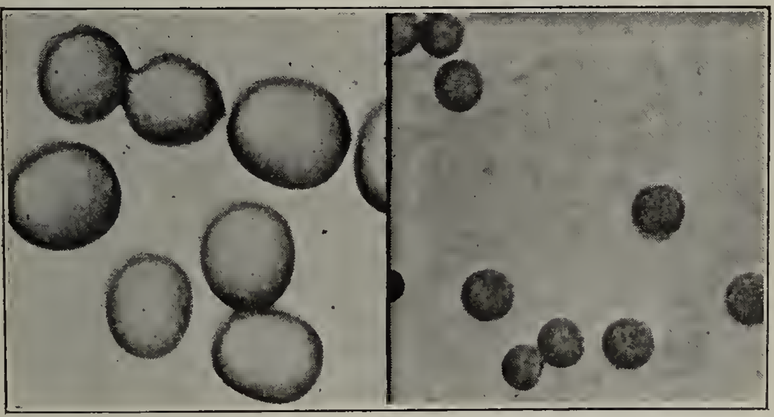

Fig. 9. Fig. 10.

Fig. 9. Pollen of Johnson grass. Andropogon helapense. Type of the pollen of the Gramineæ group.

Fig. 10. Pollen of careless weed. Amaranthus spinosus. Type of the pollen of the minor groups.

I. CHENOPODIACEÆ, OR GOOSEFOOT FAMILY.

This is a numerous family, with about seventy-five genera, fourteen of which are fairly common in the United States. There are altogether about 550 species, not more than forty of which are common. Most of them are weeds (several called pigweed), being common in cultivated or waste ground, and having a wide geographical distribution. The most important species in relation to hay fever are the following:

1. *Chenopodium album.*—Lamb's quarters, white goosefoot or pigweed. This is an annual naturalized from Europe, but now a common weed throughout North America, except in the extreme North. It blooms from June to September.

2. *Chenopodium ambrosioides.* Mexican tea or wormseed.—An annual (perennial in the Southern States) naturalized from tropical America, but now found in waste places from Maine and Ontario to Florida, and west across the continent to California. The pollen is extremely active on a sensitive subject. The period of bloom is from August to October, and the pollen may therefore be a complicated factor in the fall hay fever.

3. *Atriplex hastata or patula.*—Halberd leaved orache. It is found in salt meadows and waste places, most abundant near the coast, from Nova Scotia to South Carolina, Ohio and Missouri, and in saline soil from Manitoba to British Columbia, Nebraska and Utah, and on the Pacific Coast. It blooms from August to October.

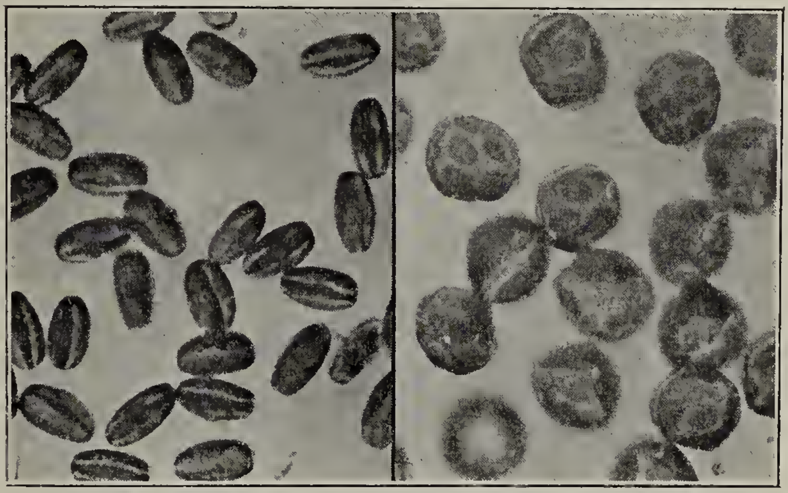

Fig. 11. Fig. 12.

Fig. 11. Pollen of water oak. Quercus nigra. Characteristic tree pollen.

Fig. 12. Pollen of black walnut. Juglans nigra. Local cause of early hay fever.

4. *Atriplex canescens.*—Bushy atriplex or sagebrush. It grows in dry or saline soil from South Dakota to Kansas, Texas, New Mexico and Mexico, and west to Oregon and California. Its period of bloom is from July to September.

5. *Sarcobatus vermiculatus.*—Greasewood. It grows in dry alkaline and saline soil, from Saskatchewan, south to California and Texas, and blooms in June and July.

II. RUMEX, THE DOCKS AND SORRELS.

These belong to the Polygonaceæ or buckweed family. A large widely scattered genus of perennial or annual leafy stemmed herbs, with about 140 species of wide geographical distribution, seventeen of which are fairly common in the United States. The most important in hay fever are the following:

1. *Rumex acetocella.*—Sheep sorrel, or sour dock. A low weed, common in dry fields and on

hillsides throughout North America except the extreme north. It is found at altitudes of six thousand feet in North Carolina. It blooms from May to September.

2. *Rumex crispus.*—Curly or narrow dock. A dark green perennial, but now a common weed in fields and waste places throughout nearly the whole of the United States and Southern British America. It blooms from June to August.

III. AMARANTHACEÆ OR AMARANTH FAMILY.

With the exception of some exotic genera, these are coarse annual weeds, with about forty genera, five of which are fairly common in the United States, and 475 species, about twenty of which are of common occurrence. They are widely distributed, and most abundant in warm regions. Some of the species, such as prince's feathers, love lies bleeding and coxcombs, are common in gardens for their conspicuous flowers. The most important in hay fever are the following:

1. *Amaranthus spinosus.*—Spiny amaranth or careless weed. A smooth, bushy branched annual, naturalized from tropical America. It grows in waste ground generally, and is common on empty grounds that has been cultivated. It blooms from April to December. The pollen (Fig. 10) is unspiculated, and measures twenty microns in diameter.

2. *Amaranthus retroflexus.*—Red root, rough pigweed. A roughish light green weed found in cultivated and waste soil throughout North America as far north as Nova Scotia, North Dakota and Washington. While only a complicating factor in hay fever in most sections, it is considered of prime importance in Arizona and the Southwest by Watson and Kibbler (5). It blooms from August to October.

3. *Acnida tamarascina.*—Western water hemp. A tall, erect annual found in swamps and moist soil from Illinois to South Dakota, Texas and West Mexico. It blooms from July to September.

IV. PLANTANACEÆ OR PLANTAIN FAMILY.

Short stemmed annual or perennial herbs, with three genera and over 225 species, of wide geographical distribution, fifteen species being fairly common in the United States. The most important in hay fever are the following:

1. *Plantago major.*—Common plantain, or henbane. A perennial common in waste places and near dwellings, almost throughout North America. It blooms from May to September.

2. *Plantago lanceolata.*—English plantain or ribwort. A hairy perennial, known by over twenty different common names in various parts of the United States, indicating its wide distribution, which is from New Brunswick to the Northwest Territory, British Columbia, Florida and Kansas. It blooms from April to November.

V. TREES.

Many of the trees are wind pollinated, and many form a cause of hay fever. The season of bloom of most of these is in the spring, so that they may form a local cause of early hay fever, or a complicating factor in the hay fever due to the grasses. Individually the season of bloom is limited to two or three weeks, and they rarely cause marked attacks, except when they grow near the residence of the patient.

While the tree pollens have been segregated in one of the minor groups, and we have found that any species of the various genera may be used to immunize against the other members of the same genus, we have not been able to select any pollen which is biologically representative of the entire group. If it is necessary, therefore, to immunize a patient against a tree pollen, the extract of a pollen of the same genus should be used for this purpose.

HAY FEVER TREES.

The trees, whose pollen may cause hay fever, are principally of the following:

1. *Quercus.*—Oaks. There are about 220 species, natives in the northern hemisphere, twenty-five of which are fairly common in the United States. Their season of bloom (Fig. 11) is from April to June.

2. *Populus.*—Poplars and cottonwoods (Fig. 6). There are about thirty species, natives of the northern hemisphere, eleven of which are fairly common in the United States. They bloom in April and May.

3. *Fraximus.*—Ashes. There are about fifty species, mostly of the north temperate zone, ten of which are fairly common in the United States. They bloom from April to June.

4. *Juniperus.*—Junipers and cedars. Evergreen trees or shrubs, with about forty species, fifteen of which are found in the United States. The blooming season of most of these is in April and May. Some species bloom much earlier, however, as, for instance, the mountain cedar, which blooms in February, and is a local cause of early hay fever in Central Texas.

5. *Juglandaceæ.*—Walnut family. This is a small family of valuable trees, the most important genera being the following:

a. Juglans, walnut. Trees with spreading branches, fragrant bark, and odd pinnate leaves. There are about eight species, natives of the north temperate zone, five of which are fairly common. They (Fig. 12) bloom during the months of April and May.

b. Hicoria, hickory. These are fine trees, with hard and tough wood. There are about twelve species fairly common in the United States, and they include the pecan, shagbark, and pignut. Their period of bloom is from March to May, occasionally to June.

Bronchial Asthma and Hay Fever with Special Reference to the Treatment of Nonspecific Cases*

By MAXIMILIAN A. RAMIREZ, M.D.,
New York.

So much has been written on the theory of protein sensitization, and on anaphylaxis and allergy in general, that I shall not take up space with a didactic discussion of these problems, which are undoubtedly familiar to all.

ASTHMA.

There are a great many types and degrees of asthma, but using the test reaction to proteins as a means of segregating or classifying cases, we may divide asthma into two groups: those giving a positive reaction to proteins which may be called specific asthmas, true bronchial asthmas, protein asthmas, or allergic asthmas, and those that do not react to proteins. In this large group, which forms about sixty per cent. of all cases, we have a type which I shall report for the first time as nonspecific asthma. These cases are true asthmas, and are due to interreaction between antigen and attached cellular antibodies; but the attached cellular antibodies are not specific, they are nonspecific and as yet unclassified immunologically, and this group does not give positive skin tests.

The acceptance of this theory will explain satisfactorily all those cases of asthma in which the patient has typical attacks and is absolutely free of symptoms between attacks. Seizures come on at regular intervals and without apparent cause, and after testing, it is impossible to find a positive etiology. In this group I should like to include cases due to protein split products, to the end products of protein digestion, chiefly among which is histamine. I shall take up this group a little later.

In further classifying cases that do not react to proteins, and which we are not including under the head of nonspecific asthma, we have the truly nonprotein or nonallergic, or atypical asthmas. In this group there are present, practically always, chronic bronchitis, decided peribronchial thickening, enlarged bronchial lymph glands, and fibrous tissue infiltration around the finer bronchi. This is also the group associated with chronic sinusitis, nasal polypi, infected tonsils, etc. Under this head we are obliged to include those cases of chronic bronchitis with asthmaticlike attacks, where the symptoms are due to plugging of the bronchi by fibrous or mucous plugs, excessive secretions, or possibly caused in part by sensitization to the protein in the bodies of the bacteria, resulting in either specific or nonspecific bacterial protein sensitivity.

In studying cases of bronchial asthma it is essential to obtain a careful history and perform a complete physical and laboratory examination. In the history, we should go carefully into the age of onset of the symptoms, for the earlier in life, the greater the incidence of true allergic asthma. The time of year at onset is important, whether or not the patient was free of symptoms between attacks, and whether the attack followed an acute respiratory infection. The family history is important, as true allergic cases seem to have a definite hereditary trend. Do not fail to go carefully into the condition of the nose, throat and sinuses, the digestion, regularity of intestinal action, and symptoms referable to endocrine dysfunction. Also, do not fail to eliminate cardiac and renal disease, hypertension, and chronic pulmonary tuberculosis.

In addition to a careful history and physical examination, one should get an x ray of the chest, a urine, stool and sputum examination, and if there is any indication for it, an x ray of the sinuses, and a culture from the nose and tonsils. The sputum should be examined, not only for tubercle bacilli, as is so often the custom, but also for predominating organisms.

A complete protein test should be performed in all cases of asthma, for though only about twenty per cent. of a large series of cases will give positive reactions, and the remaining eighty per cent. are negative, this is the only way to classify cases.

True or typical allergic asthma will give a positive skin reaction to the particular protein, or group of proteins, to which the patient is sensitive. It may be a food, animal emanation, or pollen, or a combination of these. Skin tests against bacterial proteins do not give satisfactory results; they do not seem to check up with the clinical course of the individual cases.

The most satisfactory results are in the cases reacting to the animal emanations and pollens, and the most common type o freaction is to horse dandruff, though goose feathers and rabbit hair are quite frequently seen. Rabbit hair, as is well known, is used very commonly in upholstered chairs.

Of the pollens, timothy, ragweed and corn are the most common offenders, though, of course, any hay fever pollen may cause asthma, as also with epidermals, any animal dust, such as dog or cat hair or chicken feathers may be the cause.

Of the foods, wheat, milk and egg white are the most important, and also the most difficult to eliminate completely from the diet. Active immunization against the pollens and epidermals is quite satisfactory, but against the foods it is unsatisfactory, and it is best, when possible, just to eliminate the offending food from the patient's diet.

In long standing cases there is usually an associated bronchitis, with peribronchial thickening and increased fibrous tissue formation around the finer bronchi. And this condition has to be contended with, as it is responsible for the continuation of symptoms, even after the true offending protein has been discovered and successfully eliminated. The management of this complication is similar to the treatment of nonspecific asthma, therefore I shall take it up in detail under that head.

---

*Read at St. Francis Hospital, Poughkeepsie, N. Y.

TREATMENT OF NONSPECIFIC CASES.

In the management of the nonspecific cases it is necessary to have an x ray of the lungs and sinuses, a sputum examination, and a complete stool examination. The stool should be examined for reaction, albumin putrefaction, carbohydrate fermentation and the character of the bacterial flora. If there is any evidence of sinusitis, this must be treated; if the tonsils are infected they should be removed, or treated locally. All foci of infection and absorption should be carefully eliminated.

Deep breathing exercises, in order to stretch the finer bronchi, and loosen adhesions and fibrous plugs, are very essential and should be insisted upon. The patients should be instructed to use the double blow bottles, or it may be more soothing and more pleasing to them to inhale several times a day the vapor of some soothing, oily mixture from a nebulizer.

Intravenous injections of sodium iodide give decided relief. They loosen the cough and make expectoration easier. Several injections should be given at daily intervals and then continued once or twice a week. Diathermic treatment of the chest gives some relief, making breathing and expectoration easier.

One of the best palliative measures at our command is diathermy. The treatment is given for one half to one hour, two or three times a week. Hypodermic injections of a specially prepared peptone solution give satisfactory results in obtaining more or less permanent relief. I have been using a ten per cent. solution, injecting one half c. c. daily for a week, and then increasing to one c. c. In the true nonspecific cases there is often an aggravation of the symptoms after an injection of peptone in which case it is best to diminish the dose, repeating the dose daily, however. Regulation of the diet and the ordinary mode of living is, of course, beneficial. Patients should be instructed to eat frequently and to take small quantities at a time, being careful never to overload the stomach. The main meal should be taken at noon and only a very light evening meal. Patients should be instructed to rest for half an hour to an hour after each meal, and if there is the slightest tendency to abdominal distention or gastric distress, a hot water bag or an electric pad on the abdomen during this rest period is helpful.

The stool examination will be a great aid and guide in regulating the diet. If there is much albumin putrefaction naturally it will be advisable to cut down the protein intake, and limit eggs, milk, etc. If, on the other hand, there is a great deal of carbohydrate fermentation, the starches and sugars should be eliminated from the diet. Colonic irrigations once a week seem to be beneficial in all these cases; they are definitely indicated in cases presenting symptoms or laboratory evidence of intestinal dysfunction. In cases of marked albumin putrefaction, where the bacterial flora shows an excess of colon bacilli, the administration of the bacillus acidophilus is indicated and often beneficial. Elimination should always be stimulated and it is well to advise a mild cathartic daily, such as sodium phosphate in a glass of hot water every morning. This, of course, depends on the needs of the individual patient.

We are at present experimenting with injections of histamine in an attempt to immunize actively against this protein end product in the cases where we suspect it as being an important factor. Though the improvement in the symptoms in a few of our cases has been most encouraging, I do not feel prepared to make any very definite statement regarding this form of therapy at present.

Autogenous vaccines prepared from the patient's sputum often give good results; this is particularly so in the true, nonallergic, or in the true bacterial cases. I firmly believe that better results are obtained by the use of small doses of the vaccines.

HAY FEVER.

I shall now say a few words about hay fever. Most of the cases of hay fever, or socalled vasomotor rhinitis, or pollinosis, or allergic vasomotor rhinitis, are due to sensitization to one or more of the pollens. I do believe, however, that here, as in asthma, we also have a group of cases due to a nonspecific sensitization where the patients present typical symptoms of seasonal vasomotor rhinitis, and still, on testing, do not react to any of the pollens which we ordinarily use in our tests. In these cases, as in asthma, I have obtained a definite relief of symptoms by the use of daily injections of peptone intramuscularly. There are undoubtedly cases of vasomotor rhinitis caused by proteins other than pollens, but these cases are not common. Definite nasal defects should naturally be corrected in the treatment of all cases of hay fever, but I am absolutely opposed to the removal of turbinates unless they are very definitely and extensively diseased, as I am opposd to advising hurriedly submucous resections in these cases, as the relief from symptoms is usually very shortlived. Cauterization of the turbinates and sensitive points on the septum is not a particularly appealing procedure. It is evident that measures designed to lessen local tissue irritability are very desirable, as many spasms are initiated in susceptible cases by dust, cold air, or irritating vapors.

In actively immunizing against the various pollens I believe that many of the failures are due simply to insufficient immunization, and I feel that treatment should be started at least three months before the date of the expected attack and continued right through the particular pollen season.

Bronchial Asthma Due to Mice

By WILLIAM LINTZ, M.D.,
Brooklyn, N. Y.,
Clinical Professor of Medicine, Long Island College Hospital; Physician in Chief, Bikur Cholim Hospital.

The emanations from all sorts of animals have been known to cause attacks of bronchial asthma; but there is no case on record where the emanations from rats and mice have been the cause of such an attack. It is important to bear this fact in mind when one searches for the etiology in obscure cases of asthma. The more we know of the different agents which may cause asthma, the greater will be our percentage of positive cutaneous tests, and after elimination or desensitization of the allergic agent, a greater percentage of cures will be obtained. In the following case a mouse caused attacks of bronchial asthma.

Case I.—I. J., female, thirty-six years of age, had been suffering for the past seven years from attacks of bronchial asthma, characterized by choking, wheezing, severe cough, and expectoration. There was no aura. The attacks, which were very severe, occurred four or five times a month and lasted three to five days, sometimes one or two weeks. There were no predisposing factors. The attacks occurred mainly at night, only occasionally in the daytime, and chiefly from December to March. Otherwise the patient felt well.

Seven years ago the patient was in the mountains during the summer and felt very well. She was at Rockaway Beach last summer and had no attacks. During the winter months she was at Atlantic City and felt well. If she stayed at her mother's house, a few blocks from her home, she was free from asthma. She felt better when sitting and resting, but if she lay down in her bed, she was likely to have an attack. Neither food nor weather seemed to bear any relation to the attacks, nor did the emanations from the cat, horse, or dog. She had a persistent cough during the attack, accompanied by a moderate amount of thick yellow phlegm but no odor. Expectoration relieved the attack. She suffered from marked wheezing—could not get air out of her lungs—was short of breath on the slightest exertion, even while talking or eating.

There was no nausea or vomiting but she continually belched gas, suffered from heartburn, and days of constipation alternated with diarrhea and mucus stools, which she believed was due to food.

Numerous attacks of tachycardia and palpitation bothered the patient very much, and she had flushes, chills and swelling of the feet. She suffered from nocturia and polyuria, but the genitourinary symptoms were otherwise negative. The skin presented red blotches and there was intense itching during the attack. The patient was nervous, irritable and suffered from insomnia and dull frontal headache. Her nose was always occluded, eyes and nose running, and she sneezed a great deal, especially from November to April. Menstruation had no relation to attacks; no change in periods, which were normal.

She was perfectly well between the attacks. She always belched, however, and was subject to attacks of diarrhea, coryza, running eyes, sneezing, and nocturia, even between attacks.

Menstruation began at thirteen, had always been regular, occured every twenty-eight days, lasted six or seven days, was moderate in amount, and accompanied by cramps and clots. She did her own housework, had a good appetite and was gaining in weight. Her mother had goitre, her husband and two children had eczema. There was no history of asthma. She had had measles and typhoid fever when she was young and influenza two years ago.

Examination showed that her hair was falling out. There was little hair at the outer third of the eyebrows, and hypertrichosis of upper lip and chin. Her eyes were brown, pupils contracted, and reacted to light and accommodation; conjunctivitis was present. There was no nasal obstruction. Teeth were everted, right lateral incisor notched and peg shaped; bridge and gold work present. There was also pyorrhea. Tonsils, uvula, and fauces were red and inflamed. The thyroid glands were diffusely enlarged; no bruit was heard. The cervical glands were not enlarged; mammary gland was hypertrophied. The heart was negative. There was wheezing and the lungs showed dry sonorous râles throughout. A mole and secondary adrenals were present. An examination of the abdomen showed no tumor, no masses; liver, gallbladder and spleen were negative. The extremities were edematous. Reflexes were normal. The diagnosis was bronchial asthma with hyperthyroidism.

That the case was one of bronchial asthma there was no doubt. The history was typical and the findings on physical examination were those which are so characteristic of this disease. While it was easy to establish the diagnosis, it was exceedingly difficult to establish the cause. All laboratory examination, all cutaneous allergic tests proved negative. For a time the patient continued to have her attacks and the best I could do was to relieve her with injections of one c. c. of one in one thousand solution of adrenalin. No matter what I did I could not establish the cause of the asthma.

That the cause was within the premises of her house I was sure. Was she not free from asthma the moment she landed and stayed at her mother's house, only a few blocks away? One day while examining the patient's premises, I was struck by the number of mousetraps scattered throughout the house and store. The patient lived over her husband's drug store. Upon inquiry I was informed that the place was infested with mice and rats. Then it dawned upon me that her asthma must be due to these rodents for the following reasons.

1. The attacks of asthma occurred during the period from December to March, when these rodents leave the fields and enter the house for food and warmth.

2. They occurred usually at night, when the rodents prowl about.

3. When she stayed at her mother's home, a place free from rodents, and only a few blocks away, she

was free from the attacks. When she returned to her own home, a place infested with rodents, the attacks occurred.

4. If she lay down in her bedroom, she had an attack.

5. By exclusion, all other investigations were negative. All the cutaneous tests were negative.

I therefore resolved to determine whether I could bring on an attack of asthma by exposing her to a mouse. When she was perfectly free from asthma, having just returned from her mother's home, without the patient's knowledge, in order to exclude all psychic influence, I placed a little white mouse in a box covered with gauze and asked her to smell the box. The patient said she smelled nothing and put the box on the table. In three minutes time she exhibited a very severe and typical picture of asthma. Not only did she have the marked choking, wheezing, dyspnea and cough, but also marked dermatitis broke out over all the exposed parts of her body, which itched intensely.

A very energetic extermination of the rodents was then undertaken and after the removal of a few dead rats beneath the boards of her bedroom floor, the patient was free for three years from attacks of bronchial asthma. She then moved into a fine neighborhood facing a public park. When spring came, she had her first attack of asthma in the spring time. This lasted all summer. Cutaneous tests made at this time proved that she was very strongly positive to ragweed short, a little less to ragweed tall and sweet potatoes, and less to chicken feathers, timothy and whole egg. Under proper immunization she became free from asthma.

This case proves that some of these stubborn cases of bronchial asthma in reality become pieces of research work. In some of these difficult cases, it is really necessary to familiarize oneself with the patient's environment and conditions under which he works before the true solution of the problem can be found. A striking instance of this last statement is shown in the following case: A nine year old child was brought to me suffering from severe attacks of bronchial asthma. Cutaneous tests revealed that she was strongly sensitive to lettuce, spinach, potatoes, peas and ragweed. In spite of the elimination of the above mentioned articles from her diet and the proper desensitization, she still continued to suffer from attacks of asthma. It was only after visiting their summer place and knowing that the pampas grass grew there very abundantly, that I was able to establish the fact that she was most markedly sensitive to this pampas grass. However, after returning to their permanent home the child continued to have attacks of asthma. The fact that the mother had decorated her home with the pampas grass which was then disseminating its pollen enabled me to establish a complete cure in this particular case.

Psychology of Hay Fever

By J. PAUL DE RIVER,
San Francisco.

Psychology and modern medicine are inseparable and interwoven. Success in practice depends not only upon one's medical knowledge, but also upon the use of applied psychology. Keen attention to the temperament and actions of every patient frequently enables one to differentiate the stable brain from the psychoneurotic or imaginative genius. To do this one does not have to be a specialist in psychology, nor does he have to enter the class of charlatans and sympathetic healers. One's sense of judgment, together with an understanding of a few fundamentals of normal psychology, is all that is required. Imagination accompanies every ailment, no matter of what nature it may be. At times, however, the degree of imagination is in excess of reason and will power to control. In the struggle for supremacy which follows, will usually succumb to imagination.

It is then we meet the psychoneurotic. This particular class of patient is encountered by every physician. In ophthalmology and otolaryngology we have our share. They are not limited to any particular class, nor does sex seem to play any part. In the front ranks of this army of psychoneurotics stand the sufferers from hay fever. Hay fever in itself is a true vasomotor neurosis, and its sufferers are either primarily psychoneurotics or manifest a secondary psychosis following the hay fever attack. There is no condition that the ear, nose and throat specialist encounters in which the nervous element plays such a conspicuous part. In fact, nearly all states of functional insanity are at one time or another experienced by the sufferer, from the irritable and excitable states to the depression of melancholia. Fixed ideas and phobias are but a part of the syndrome.

The hypersensitive condition of the nasal mucosa leads to an overstimulation of the sneezing centre, resulting in this act becoming automatic. Without his will the patient sneezes, due to lack of inhibitory control.

Then comes the excess of imagination. He has ideas that in certain localities his condition is provoked. The mere thought or suggestion of his condition stimulates his sneezing centre (thought stimuli). These sufferers live in a state of obsession. Drafts, smoking, street cars and trains may all bring on an attack. This state of obsession continues in a more or less degree throughout the whole hay fever season, and in many the act of sneezing has become implanted in the subconscious to such an extent that the mere thought or mention of a trip on the train, or a visit to a special locality will bring on an attack. What are we to do for these patients? Assuming that the primary condition is hay fever, and acknowledging that it is in itself due to some disturbance in the vasomotor system, as a rule ingrafted upon a psychoneurotic diathesis. This leads one to ask, first, are we to treat the condition locally? Second, if local treatment is used alone, can we expect to gain results by ridding the patient of an element which is psychoneurotic? And third, shall we use a combination of both methods, viz., the treatment of a local condition furnishing symptomatic relief together with the intelligent use of psychotherapy? The last method I am indeed partial to, and we, as otolaryngologists, find it our duty to attack nasal pathology, correcting all deviations from the normal in order to restore the physiological functions as near as possible. The application of pollen antigens when indicated, local applications of medicinal substances, the surgical correction of all anatomical defects of the nose and throat, and the proper use of psychotherapeutic measures are indispensable adjuncts. Only by recognizing the psyche, which is the directing force, and realizing that the spirit, soul and body are inseparable are we able to treat the whole human being scientifically, with the hopes of gaining results.

Tonsillectomy.

Electric Coagulation and Desiccation

By A. M. MAC WHINNIE, M.D.,
Seattle, Wash.

Theories regarding the function of the faucial tonsils are many and varied and so far but one is accepted clinically. There is no dissension, clinically, from the belief that the tonsils furnish a secretion for the lubrication of the pharynx and act as a support to hold out the pillars in their advanced position in the pharynx. The ablation of the tonsil and its capsule obliterates this function completely or partially and the arch atrophies, as well as the palatoglossus and palatopharyngeus muscles. There is a widening of the faucial space and at the same time a loss of action of the soft palate, tongue, and larynx. It is only on account of these functions being compensated by other tissues that the voice retains some of its quality. Even so, the throat tires more quickly than under normal conditions and dryness is frequently complained of.

The prime object of the palatopharyngei muscles is that of controlling the pitch of the voice with the superior cornua of the thyroid cartilage serving to tilt the cartilage forward, thus tending to stretch the vocal cords. The characteristic resonance of the cavity is largely determined by the size, shape, and contents of its resonance chambers. It follows, then, that the lymphoid tissue in the nasopharynx, oropharynx, and larynx goes far in determining the characteristic resonance, thus giving to the voice its distinctive features. The voice can only be normal when this lymphoid tissue is normal; the degree of impairment depending upon the degree of enlargement of the tissues forming the contents of the chambers.

In reviewing the literature, one is impressed with the various opinions of the different men as to what is an infected tonsil. One can only conclude that no precise and definite standards have been accepted. One authority considers more or less congestion, with a spongy appearance produced by edema over the surface of the tonsil, as evidence of infection. Often patients with arthritis will state that they have never had tonsillitis or sore throat, yet on pressure the tonsil will disclose pus. Yet we find Makuen stating that a mere congestion of the pharynx, or even an occasional tonsillitis, is not sufficient reason for the removal of the tonsils, as the cause of the disturbance may be in some remote part of the body. Makuen's statement corresponds with my experience, for we well know that at the present time, with the short order meals, the unbalanced diet and poor nitrogenous elimination are responsible for the low resistance of the pharynx, making it amenable to infection.

The treatment of tonsillitis seems today to be based upon infection. Yet we know that if the chemical system of the individual is at par, such infection does not usually take place, except from traumatism. It is true, that many physicians are removing tonsils where the color of the throat is normal, the size of the tonsils seeming to be the only reason for their removal. The question resolves itself into what constitutes the cardinal indications for tonsil removal. There are no definite criteria for what constitutes the cardinal symptoms for finally determining the necessity for removing the tonsils; each individual physician uses his judgment. The various medical organizations should establish a standard, after a committee investigation, as to what should constitute the definite signs for tonsil removal. Probably this is asking too much. All textbooks, published after the report of this committee has been submitted, will make use of it and place the tonsil operation on a definite scientific basis. Pick up any of the textbooks and the reasons for tonsil removal vary from redness of the throat, enlargement of the tonsil, voice fatigue and anemia, to secretion from the tonsils. With such a variety of opinions, it is not to be wondered at that the tonsils are removed wholesale for each new ailment of the body. The clinical results, as shown by the reports of Simpson, Blauner, Orgel and Kaiser, showing the end results from one year to a year and a half after operation, give us a concrete idea upon which we can conscientiously base the final results of tonsil eradication, one year postoperative being a good time to make a just and honest comparison with the preoperative condition.

We know from these reports that tonsillectomy does not insure against further attacks of sore throat, infections, and other diseases for which the operation was done. The results reported by Girard College of operations for sore throat, mouth breathing, and impaired hearing, show an improvement in scholarship, voice, and health varying from fifty-eight per cent. to ninety-five per cent.; the ninety-five per cent. improvement being in the quality of the voice, which speaks well for the character of the surgery.

My method of determining whether the tonsil should be removed is as follows: first, ocular inspection; second, making a culture from the crypts of both tonsils, compressing the tonsil for the possible presence of pus in and around the tonsil, to find the predominating bacteria, usually streptococcus and staphylococcus of the various species and occasionally diphtheroid; third, chemical blood analysis, urea, uric acid, nonprotein nitrogen, creatinin, and blood sugar; fourth, Wassermann and Noguchi tests; fifth, blood pressure; sixth, x ray of the pituitary body, for we must not overlook the fact that the late Dr. Joseph Fraenkel repeatedly pointed out the functional connection between the glands in the cranium and the glands in the throat, and the hypophyseal tissue in the upper part of the pharynx from which part of the embryo the pituitary gland is subsequently developed. He considered that the tonsils, pituitary, and appendix were functionally related. His conviction was so strong in the utility of the tonsil and its protective influence on the appendix, that he refused to believe that a suppurative appendix existed in a patient where the tonsils were intact. According to him, only when the tonsils are destroyed by disease or removed by the surgeon is pus in evidence in the appendix. This is food for greater thought than we have at present time given to the tonsils.

When we have definitely established that the tonsils are the seat of the infection there is but one course to pursue—treatment of the blood chemistry and a complete eradication of the tonsils by some method that will leave the throat with as great or greater functioning power than existed previous to the operative procedure. The consensus of opinion is that the operative procedure of choice is one in which the tonsillar capsule, so called, shall be left intact and thereby retain as near as possible the complete functioning power of the palatoglossal and palatopharyngeal muscles. Following the sharp cutting operations, we have all been chagrined to see the various deformities amounting almost to distortion, rapid tiring of the voice following speaking, as well as of the individual physically, so that many speakers, who previously had been able to speak for an hour at a time, found themselves completely prostrated after fifteen minutes' speaking. Kenyon asserts that ninety-five per cent. of the patients who have been operated upon by the cutting method show a deformity of some kind. This must strike one as very strange, for of all operators upon the tonsils in this country surely more than five per cent. are first class. Many of us have dissected out most beautifully the tonsil and its complete capsule with apparently no injury to the palatoglossus and palatopharyngeus muscles or the superior constrictor, congratulating ourselves on the beautiful result, and then, at the end of say three months, are chagrined to see the fossa fill up level with the pillars, retarding their action. In the cases where this does not take place, a gradual thinning out, an atrophy of the palatoglossus and palatopharyngeus muscles, takes place with loss of functioning power in the voice from lack of capsule support.

One of the most annoying sensations following this, especially in adult patients, is the tiring of the throat which affects both phonation and articulation and the inability to protude the tongue as far as before the operation. These two muscles are highly developed in singers and professional voice users and they serve in a great measure to regulate the relative positions of the tongue and soft palate in voice production. They also indirectly affect the action of the laryngeal muscles by helping to control the palatal and lingual positions during the phonatory action of the vocal cords and other portions of the larynx. We even find many patients who have lost their voice control and been obliged to give up lucrative positions for others less remunerative. One writer states that he does not believe it is possible to remove the capsule intact, as it is of fibrous material and covered by the superior constrictor muscle, and the fulcrum upon which it acts being without scar tissue and adhesions, the superior constrictor muscle is held down, with the result that many patients complain of difficult deglutition.

In operative procedures upon the tonsil one must never lose sight of the accidents which may occur. The anomaly of the arteries in elderly patients; children in whom the thymus gland is still large; the possibility of hemorrhage in proportion to the clotting time of the blood and blood pressure; pulmonary abscess; anterior dislocation of the atlas; pain in the tonsil region, neck, and larynx, said by Justus Matthews to be due to the larger branches of the glossopharyngeal nerve being injured.

What shall be the operation of choice? One in which the loss of blood and shock is reduced to a minimum and in which the patient will be better off physically and the voice equal to or better than before the operation. No cutting operation that removes the entire capsule can give as good a result as one in which there is a complete removal of all the tonsillar tissue leaving the capsule intact. Those who have done thousands of these tonsil operations and witnessed a large amount of cicatricial contraction and palate deformity, are convinced that a method should be used for the enucleation of the tonsil with the smallest possible amount of traumatism and the least amount of capsule destruction that will give a satisfactory result, avoiding all the conditions mentioned above. If all the capsules, so-called, were of uniform thickness, we would be able, by careful dissection, to remove that portion of the capsule which is in intimate contact with the tonsillar tissue, and thereby obtain perfect results. But some of these are thin and some are thick, consisting of several layers of fibrous tissue which can be pared off like the layers of an onion. Age does not make any difference in the thickness of the capsule, generally speaking. It does add some thickness but is not consistent with the age of the patient. With the intimacy that exists between the capsule and the superior constrictor muscle and the dangers that attend cutting operations, a procedure that will eliminate all tonsillar tissue and leave the capsule intact to act as a supporting membrane to the superior constrictor, glossopharyngeal and palatopharyngeal muscles is the ideal method for eradication, with the highest possible physiologically functionating throat. Makuen states that he believes leaving the capsule intact is perfect surgery. No cutting operation that involves the removal of this capsule can insure the operator, as well as the patient, that he will have a throat which will function physiologically.

In removing the tonsils, we find that there is pus formation in or around the tonsils, with the result that a certain amount of absorption of pus into the system takes place, evident for a week or ten days, sometimes longer. Any procedure that will eliminate this it seems to me, is ideally perfect. We must never forget that we are operating up into the cervical region and it has happened that serious infection has resulted from opening this area. In reading over operative procedures, we find numerous instances where most operators make an anterior and posterior incision cutting through into the intrapharyngeal aponeurosis, thus taking away one of the supports of the anterior and posterior pillars.

It may seem presumptuous on my part to offer a new method for tonsil eradication, leaving the capsule intact, when there have been so many tonsil operations recommended, but only after six years' use is it offered.

With electrodesiccation or thermocoagulation all the difficulties enumerated can be avoided. One must remember that the equipment should not consist of a box such as that sold by some manufacturers. One must have a machine of ample power with a hot wire milliamperemeter so that the current can be measured accurately. Experience alone will give one the desired information as to the length of time the current should be applied and the number of milliamperes required for a thorough eradication of all tonsillar tissue. The variation in the amperage is from one hundred to one thousand milliamperes, depending upon the consistency of the tonsillar tissue and its depth. Roughly speaking, eight hundred milliamperes suffice with the active electrode well inserted in the tonsil and the indirect electrode in any other part of the body for a period of forty-five seconds; two or three sittings are usually sufficient.

Electrical desiccation by the unipolar method will necessitate a large number of treatments and after each sitting it may be necessary to use any of the ordinary curettes to take away the necrotic tissue. This method is not as desirable, owing to the fact that the spark may jump to any part of the oral cavity, especially if the uvula is elongated and has a tendency to swing laterally. However, the ultimate result is perfect. With the coagulation method the tonsillar tissue disappears in about ten to fourteen days following the last application, while with the desiccation method four weeks are usually necessary for complete eradication, depending entirely upon the thickness of the tonsil and the amount of application made at each sitting. It can be stated that this method is absolutely painless.

Industrial Eye Injuries*

By FRANK ALLPORT, M.D.,

Chicago.

(First Communication.)

The substance of this paper should be considered under two headings, viz., prevention and cure. Let us first endeavor to ascertain what can be accomplished in the way of prevention of ocular injuries in industrial occupations.

1. PROPER EXAMINATION OF EYES PRIOR TO EMPLOYMENT.

One of the most important barriers to eye damage is a thorough examination by an oculist before an applicant is given employment. It is not sufficient to have such examinations made by a general practitioner, a nurse, or a layman, who merely tests vision with test types and makes a general or cursory survey of the eyes. Many important pathological conditions are only detectable by an experienced observer. Slight strabismus, minute corneal, vitreous and lenticular opacities; hidden iritic adhesions, fundal changes, abnormal visual fields, refractive errors, can be detected only by the experienced oculist—and it is these very conditions that are important to diagnose. It is essential that one should be cognizant of such abnormalities and possess records of the findings. It may be altruistic to assume the honesty of all men, but we who are disillusioned know that all men are not honest. My own experience leads me to believe that only a minority of men are honest when it comes to seeking financial remuneration for physical damages from rich corporations. Indeed, I am not perfectly sure I would not be dishonest myself under such circumstances. I suspect I should enlarge upon all possible physical ailments, feeling that after all I had worked hard for the company and had been damaged while in its employ, that there was no telling what might happen as a result of my accident, that I had a family to support, that the company was rich, while I, who did their dirty work, was poor, and, after all, why should I not get any money I could, without leaving behind any very strong conviction of real dishonesty. If, therefore, I, a reasonably honest, and I trust a reasonably intelligent man, could under stress of circumstances dally with the truth, is it not reasonable to assume that others, less endowed than I, would do the same? Thus it happens that industrial surgeons (particularly) are constantly brought into contact with more or less spurious demands for financial compensation for bodily damage, and one definite means of defeating such spurious claims is to have accurate physical records of all applicants for work, before work is assigned.

---

*Read before the Chicago Society of Industrial Surgeons, November 6, 1922.

Not infrequently I see patients who have sustained some trifling eye accident, who at the same time have a senile cataract. Blindness as a result of the accident is the claim, and yet I know that there is no possible connection between the two conditions. The report of a proper physical examination, before employment, would probably clear up this claim at once, especially if physical examinations were required at intervals of, let us say, every two or three years. Men seeking employment invariably represent their vision and hearing to be of the best possible quality. They want work and they do not underestimate vision and hearing. But when they seek compensation for injuries they represent these functions to be as poor as possible, for reasons that are obvious to all. I, also, occasionally see patients, who have sustained a slight head contusion, in a few days complain of a bad smelling, discharging ear. An examination discloses an almost complete absorption of the drum head, and much necrosis and granulation tissue, conditions it takes months or even years to develop and conditions which, of course, have nothing whatever to do with the head contusion of a few days previously. These cases would have no standing in court if previous reports of such ear disease could be produced. Proper physical examination of applicants for work should be made before men are placed at occupation. Such examinations would cost something, of course, but not so very much after all, and it is, in reality, a form of insurance a business man cannot afford to ignore, for it will surely save him thousands of dollars in due course of time by being in a position to defy many spurious claims for damages. Employers should regard such examinations as a legitimate and necessary form of insurance.

Proper eye and ear examinations prior to employment will exclude from factories, etc., applicants suffering from contagious diseases, such as trachoma, hypertrophic papillary conjunctivitis, foul discharging ears and other contagious diseases, thus lessening the diseases in shops and the legal liabilities attendant thereon, to say nothing of the diminution of human suffering and disaster.

It must also be remembered that the most efficient and valuable services from workmen can be performed only when men are in the best physical condition and are working under the most advantageous circumstances. The physical examination of applicants, before employment, discloses their weaknesses, discards some altogether, and enables the employer to place those who remain at work in places harmonious with their defects, thus enhancing their value as working units and also permitting the employee to seek medical or surgical advice for the correction of (perhaps) unsuspected diseases. For instance, a man who has poor eyes can, perhaps, be fitted with glasses, or undergo treatment or operation for his relief, and can also be given employment somewhat consistent with his infirmity. A man whose ears have been found diseased or defective can seek the advice of an aurist, and be placed at work where good hearing is not necessary to successful employment. Thus it will be seen that proper physical examination before employment, and at subsequent suitable intervals, is not only valuable to the employer in protecting him from fictitious claims for damages, and in enabling him to obtain better and consequently more profitable labor, but it is also beneficial to the employee because it discloses defects and diseases and enables him to seek relief, and it also prompts his employer to give him work harmonious with his physical condition. The only thing it antagonizes is dishonesty and this furnishes no excuse for doing the right thing.

2. ILLUMINATION.

The proper lighting of shops is unquestionably of very great importance in the prevention of accidents and is a subject that is constantly assuming larger proportions in the minds of shop owners, architects and illuminating engineers. Insufficient illumination can undoubtedly produce diseased ocular conditions, but so also may excessive and improperly directed illumination. Daylight is the best illuminant and should be utilized as much as possible. The next best illuminant is the one that most nearly simulates daylight. Illumination should be ample but not excessive as too much light may be as injurious as insufficient light. Not only should illumination be ample and proper, as provided by enormous window spaces and by the best kind of artificial illumination, but the lighting should be properly directed so that each bench, wheel, vat, machine, etc., is individually well lighted and shaded so that the men can see distinctly and work without ocular effort, and almost automatically. Some shop owners with semiliberal minds, restrained by economical restrictions and possessing conceit, assurance and determination, equip their shops with illumination according to their own ideas, unhampered by the scientific and experienced advice of an illuminating engineer. They are, perhaps, determined to do the thing on a big scale and they install lights and plenty of them, in short their lights are an injury and an embarrassment to the employees. They are bad for the eyes. There is, perhaps, too much light, or at least it is improperly and unscientifically placed. It stares you in the face, it is dazzling, it makes work hard. Illumination should be ample but not excessive. It should be evenly diffused and should not fall directly into the eyes. It should come from above, behind and from the left. It should not throw shadows on the work. Bad lighting forces the workmen to pay too much attention to seeing distinctly. This should be done without effort, thus enhancing his value by increasing his output and, incidentally, saving his eyes.

Improper illumination produces mistakes in work, wastage of material, and a greater liability to accidents. Twenty-five per cent. of shop accidents are produced by improper illumination, and the least number of accidents occur in July and August because these months furnish more daylight than any other months in the year. The proper lighting of steel mills increases their output two per cent. and in textile and shoe factories the increase is ten per cent. It only costs about one quarter of one per cent. of a man's wages to light a shop properly. Thus, if a man earns three dollars a day, it will cost about one cent and a half a day to furnish him with proper illumination.

Shop owners should employ illuminating engineers to install their lighting; it will be cheaper in the end. Such men are quite agreed as to the superiority of the tungsten lamp. Its light closely resembles daylight and is cheap and durable. They should be supplemented with white porcelain enameled reflectors, and the entire lighting system should be kept clean. White walls and woodwork and clean windows will add about thirty per cent. to the efficiency of natural or artificial illumination.

3. SHOP GOGGLES.

I am happy to say that shop goggles are being worn more and more by shop workers. Not very long ago most men almost disdained the wearing of goggles. Some felt it was cowardly, others said they were a nuisance, interfered with their work, became easily fogged, etc. Almost all shops were glad to furnish goggles, but most of them remained in the shop unused. Many of the men are densely ignorant foreigners whose mental habit refused to adopt innovations. The habit of wearing goggles gradually grew, inspired by educational pamphlets, talks, notices, pictures, etc., and now a vast majority of workers in shops wear goggles. They have learned that it is a good thing, that it saves the eyes, that it is a necessity. The Pullman Company declares that thirty-five per cent. of shop injuries are eye injuries and that most of them could have been prevented by the wearing of goggles. There are many kinds of goggles on the market, but the best are the Saniglass goggles. They fit well, have side shields, and the glass is clear, thick and very strong. The glass can, of course, be ground to correct the workman's refractive error, if he has any, and can be colored in any tint to harmonize with the man's occupation.

In the American Steel Foundries shop eye accidents were reduced seventy-five per cent. in two years by wearing such protection. In order to give an idea as to the kind of occupations producing the most eye accidents in the ordinary steel shop, I will say, 1, that undoubtedly hammering produces more eye accidents than anything else. Then comes, 2, emery wheels; 3, molten metals; 4, electric flashes; 5, riveting; 6, machine tools; 7, bursting of water and lubricating glasses, and, 8, belting.

4. TOOLS AND PROTECTIVE DEVICES.

Improper tools and the absence of suitable protective devices for machines, produce many eye accidents.

Most hammering accidents are caused by using tools with burred or mushroomed edges. When such tools are used steel particles are easily broken off and fly with great velocity into the eye, producing serious consequences. Tools should be kept in good condition and when the edges become even slightly mushroomed, they should be immediately repaired, a precaution which will save many eyes from blindness.

Modern shops are being more and more furnished with all kinds of safety devices, for they have been found to be both beneficial and economical. Shops should be kept cool, clean, light, and as nearly dustless as possible, for men can accomplish more and work better under such circumstances. Emery wheels should be protected by glass or leather guards or hoods, and dust particles should be sucked away by an exhaust system. Emery wheel accidents are very frequent and some men who work at emery wheels have their corneas speckled by the oft repeated assault of emery wheel particles. I have seen the glasses or goggles of emery wheel workers speckled so that they looked almost like glazed glass, so often have the glasses been struck with flying particles.

Vats containing molten metal should be handled carefully and should be surrounded by protectives. Goggles, or, still better, leather masks with goggles, should always be worn when handling molten and babbit metal, for burns from splashing molten metal are most gruesome and discouraging in their character.

Electric flashes can be avoided by using enclosed switches and fuse boxes. Riveting and punching machine accidents can best be avoided by care and the use of goggles. Milling machines, shapers, etc., should be protected by what is known as glass chip guards. Water and lubricating glass accidents can be much reduced by using the very best glass and by protecting the glass with suitable guards as the contents are under constant and strong steam pressure.

Eyes are sometimes injured by being struck with broken belting caused by improper jointing. Endless or glued joint belts should be used instead of hooks or lacings to make a joint. Belts should never be replaced on a pulley by a stick as is so frequently done. Serious eye accidents sometimes result from such practices. Excessive light or heat in shops, particularly steel shops where electric welding is done, may produce retinal and other eye injuries. The temperature and light in these furnaces is tremendous. Cast iron furnaces possess a temperature of 2,000° F., and in electric welding the temperature may rise to a height of 12,000° F. Such heat and glare may produce retinal and optic nerve changes and burns of the skin, conjunctiva and cornea. Screens of blue or red glass should be used and the workman should wear an aluminum helmet. Retinal changes may occur from grinding carbon or manganese steel, where the worker looks constantly into a steady stream of sparks and while doing this work amber goggles should be worn. Amber goggles should be worn by glass blowers to prevent cataracts and by silver burnishers, who look protractedly upon highly polished surfaces, to prevent retinal changes. Goggles should be worn when the oxyacetylene torch or electric are in use.

5. THE SHOP OCULIST.

The individual who has come to be known as the shop oculist deserves a section all to himself, as he is one of the greatest menaces to eyesight in the average shop. Fortunately the public has become considerably educated concerning such matters and the career of the shop oculist is on the wane. He still exists, however, in many shops and until he is utterly exterminated, the propaganda against him should continue. He is one of the great body of workmen who has acquired an undeserved reputation for removing foreign bodies from the eyes of his brother workmen. He is ready at any time to suspend his dirty work, and with unwashed hands, endeavor to remove a particle of any nature whatsoever from the eye of some unfortunate workman. He proceeds to his unwarrantable work, as I have said, with dirty hands, with conceived assurance, with poor illumination and tools, and without lenses and cocaine or adequate knowledge. Sometimes his efforts are successful and harmless and this, of course, adds to his assurance, egotism and reputation. But frequently, alas, in endeavoring to remove a tightly driven foreign body from the cornea, with dirty hands and tools, with improper illumination and a moving and roving eye and without cocaine or antiseptic precaution, he only succeeds in mutilating and infecting the cornea and, finally, after having done his best, or, rather, his worst, advises the injured victim to do, what he should have advised him to do at the start, viz., go at once to a competent oculist. The appearance of such eyes when they come into my hands is often appalling, and require heroic treatment, but at the best a large scar usually remains which more or less impairs vision in accordance with its density, extent and location. But many of these cases go on to a violent infection, ulceration, hypopyon, panophthalmitis, and enucleation. It seems to me, as I look back over a large and varied experience of ocular accidents, that I have seen more eyes destroyed by the improper initial treatment of minor injuries than from any other one cause.

The removal of foreign bodies from the cornea should be considered a serious affair and should not be undertaken by laymen or general practitioners. I hope I do not offend my general practitioner friends when I say this but, as a rule, they have no more qualifications to do this work than I have to treat measles or mumps. Some particles are easily removed from an unanesthetized cornea, but most of the invaders have to be dug out with a spud or a cataract knife and herein consists the danger. They should be removed under strict aseptic precautions by an experienced and steady hand with proper illumination and lenses, and with the infliction of as little damage to the cornea as possible. This is frequently a tedious and nerve racking affair and only experienced and patient ophthalmologists are adapted to the work. Foreign bodies are sometimes deeply imbedded, and are almost impossible of removal, even by the exercise of great skill, experience and tact, and the use of fluorescin to outline the site of injury. Such injured men should be given the best chance for the preservation of vision and such an opportunity does not follow the ministrations of the shop oculist, shop nurse, and I am sorry to say, not always the shop doctor. Such cases should be sent immediately to a competent oculist, thus saving eyes, vision, suffering and expense.

6. DANGER TO VISION FROM CERTAIN OCCUPATIONS.

Attention should be paid to the fact that certain occupations are likely to injure vision and every precaution should be taken to prevent this disaster. For instance, dinitrobenzine, which is used in manufacturing aniline dyes, injures vision by inhalation, which can be prevented by ample ventilation or by using closed mixing vessels. Bisulphide of carbon, used in vulcanizing rubber, produces a vapor which injures vision by producing retinal and optic nerve changes with a very poor prognosis. Nicotine may be absorbed in tobacco factories, with characteristic ocular symptoms. Amblyopia may develop in both tobacco workers and tea tasters. Paper hangers, painters, workers in arsenical preparations, etc., demonstrate the fact that arsenic is absorbed principally through the respiratory tract, producing eye pain and irritability, optic neuritis and atrophy. Eyes are damaged in plumbers and painters where lead is used. Lead enters the body through the fingers and lungs. Headaches, poor vision, scotoma, ptosis, paralysis, etc., are noticed. Carbon monoxide very occasionally produces optic nerve and retinal disturbances and paresis of the ocular muscles.

Most of the ocular disturbances from chemical causes can be avoided by strict cleanliness, especially of the hands, and by thorough ventilation. Wood alcohol is used in many industries and workmen should always be acquainted with the fact that they are dealing with a deadly poison, capable of producing blindness from optic nerve atrophy, and even death. It is used, for instance, in cleaning off shellac from the interior of beer vats, where the fumes become very strong, especially when the ventilation is poor. This menace can be combatted by using as little of it as possible, and by extreme cleanliness and thorough ventilation.

High explosives in mining, railroad construction, etc., produce many serious eye accidents. Bursting bottles in charged water factories and lime burns in masons, bricklayers, plasterers, etc., often produce disastrous ocular damages. Great care under such circumstances, with a full realization of the damages involved, will prevent many sad accidents. The eyes of miners are not only threatened by explosives, in dislodging coal, but by nystagmus from working underground with insufficient illumination and from working while lying on the back. Mines should be abundantly lighted, abnormal postures while at work should be avoided, errors of refraction should be corrected, the health should be kept up to the highest standard, and the hours of submerged work should be as short as possible.

Certain occupations, involving exposure of the eye to heat and light, may produce slowly developing cataracts. This is conspicuously the case with glass blowers but may also occur in any industry where the eyes are exposed for long periods of time to intense heat and light. The greatest protection consists in wearing thick colored glasses that disperse both heat and chemical rays.

I am well aware that this paper has not completely covered the subject. It would have to be much longer to do this, and I did not feel at liberty to occupy too much time. Enough has been said, however, to demonstrate that almost all occupations possess dangers to eyesight that should be thoroughly understood and carefully guarded against. But before closing this article I wish to say a few words for the benefit of the great army of office workers whose eyes are being damaged by protracted work on books and papers by poor illumination, and without having their eyes properly corrected by glasses, perhaps purchased at a place where examinations are free. All of these details should receive proper attention by those who are earning a living by visual work performed in an office or store.

In a later paper I intend considering the treatment of eyes that have been injured in industrial occupations.

7 West Madison Street.

An Analysis of Twenty-nine Cases of Uremia*

By HENRY M. FEINBLATT, M.D.,
Brooklyn.

Before the days of blood chemistry, the term uremia was used to designate a group of symptoms which usher in the fatal ending in a large proportion of cases of renal disease. Hence a protean symptomatology, dependent upon varying underlying causes, was scrapped together and placed under the common caption of uremia. Efforts to discover the cause were largely unsuccessful, because no one experimental or pathological condition could account for the whole picture.

Von Wilson (1) in 1833 described the syndrome and attributed it to urine retention following renal insufficiency. At about the same time Bright (2) and his coworkers, Bostock and Christison, demonstrated an actual increase in the urea of the blood in this group, and, believing this substance to be the toxic agent, called the condition uremia.

Much investigation has been carried on with the other urinary substances, and each of the different constituents has at one time or another been designated as the toxic product. That no one of the contained substances known is the causative factor is now generally admitted. The complex is attributed to all of the retained noxious products normally excreted.

Uremia due to total ablation of renal function closely simulates the condition obtained in experimental animals but differs widely from the common description. I have had an opportunity of studying four such cases; one case of surgical removal of the kidney in which the other kidney was functionally useless; one case of bilateral impaction of the ureters with calculi; two cases of anuria due to bichloride poisoning.

Headache, increasing drowsiness gradually merging into coma, muscular irritability, increased tendon reflexes, restlessness, vomiting, and ammoniacal breath comprise the clinical picture. Conspicuously absent are convulsions, amaurosis, transient paralyses, and delirium.

These latter evidences are now admitted to occur in the eclamptic type and to be due to other causes than nitrogenous retention. Volhard (3) adheres to Traube's old view and ascribes them to cerebral edema. There is abundant confirmation of this theory. It has been repeatedly observed that the spinal fluid is under increased pressure and that rachiocentesis is followed by diminution of convulsions and marked amelioration of the mental symptoms. Necropsy reveals edema of the meninges and of the cerebral cortex. Hemiplegic and amaurotic patients have shown after death focal edema of the precentral and cuneate gyrus respectively. Widal has demonstrated chloride retention and ascribes the edema to that factor. In 1916, Foster (4) announced that he had isolated a crystalline, convulsive toxin.

Under the term azotemia, Widal describes the syndrome of nitrogenous retention due to renal inadequacy. The author concurs with him in the belief that the term uremia should be limited to this group of cases. The phenomena due to other causes should be separated from this category and the caption uremia narrowed to the clinical picture of retention. Considered in this light, uremia is chiefly evidenced by the blood chemistry and nitrogenous retention is a *sine qua non*. A distinct type is represented as regards cause, clinical course, prognosis, and indications for treatment. Inasmuch as the textbook descriptions of uremia include practically all serious manifestations found in nephritics, it is felt that the study of a series of cases of nitrogenous retention is in order. To include under the same heading disturbances due to cerebral edema, arteriosclerosis, cardiac decompensation, and other factors is confusing and often misleading.

Twenty-nine cases of uremia in the wards of the Long Island College Hospital were studied according to a definite scheme. The purpose was to take another point of view. Instead of considering the blood chemical analysis as confirmatory of the clinical picture, a series of cases of known chemical uremia was collected and the findings were analyzed with an unbiased attitude. The criterion of the presence or absence of uremia was the blood chemistry. This report includes all cases due to kidney insufficiency in which the blood urea nitrogen rose to fifty mgms. to the hundred c. c. or more.

The data tabulated in these cases are summarized under the headings blood chemistry, etiological factors, symptomatology, urinary findings, blood findings, eye signs, cardiovascular changes, complications, and outcome.

BLOOD CHEMISTRY.

Normal figures: Urea nitrogen 12-15 mgms. per 100 c. c. Uric acid 2-2.5 mgms. per 100 c. c. Creatinin 1-1.5 mgms. per 100 c. c. Sugar 90-110 mgms. per 100 c. c.

These determinations were all made according to the method of Folin and Wu (6). Ten c. c. of blood are sufficient for determination of all four ingredients. Folin's method was chosen because of its greater simplicity and its accuracy. In the sugar estimations comparative tests were made with the old and new Folin methods and the readings were found to coincide. It was a routine procedure to draw the blood before breakfast and to make the analysis the same morning.

In this group urea nitrogen is the most constant of all the nonprotein nitrogen ingredients and furnishes the most reliable index to the progress of the disease. Uric acid is the most variable factor, and, while always increased, does not rise in the same ratio with urea nitrogen. In case No. 22 the uric acid was only five mgms. to 375 mgms. of urea nitrogen, while in case No. 11 the uric acid measured fifty mgms. to 300 mgms. of urea nitrogen. Creatinin bears a more constant relation to urea nitrogen and tends to increase in the same ratio. Sugar values appear to bear no relation to retention of nitrogen. Even in cases where the urea nitrogen rose to 375 mgms. the sugar values were very frequently within normal limits. In those cases where the sugar content was above normal, this finding was apparently due to decreased tolerance rather than to retention. Experimenting by adding known amounts of creatinin and uric acid, the author was able to satisfy himself that sugar readings with Folin's method were not influenced by retention of these substances.

---

*From the Clinical Laboratory, Department of Internal Medicine, The Long Island College Hospital, Brooklyn, New York.

ETIOLOGICAL FACTORS

Family history. A history of nephritis in the ascendants was obtained in only three cases.

Sex. There were twenty males and nine females. These figures are approximately proportional to the relative rates of admission to the medical service for the sexes.

Age.—First decade, 0; second decade, 1; third decade, 12; fourth decade, 4; fifth decade, 7; sixth decade, 3; seventh decade, 1; eighth decade, 1.

Thus twenty-three cases or seventy-nine per cent. appeared between the ages of twenty and fifty. Only one instance occurred before the age of twenty. In younger patients true chemical uremia is unusual. Here symptoms due to cerebral edema complicating acute glomerular nephritis are the rule. The distinction is of supreme importance in prognosis.

Occupation. A study of occupation revealed no apparent relation to the condition.

Underlying renal condition.—Chronic glomerular nephritis, 18; mixed type, chronic glomerular nephritis plus nephrosis, 4; necrosis due to bichloride poisoning, 2; amyloid kidney, 1; nephrosis, 1; acute glomerular nephritis, 1; arteriosclerotic kidney, 1; nephrectomy, one; kidney functionally useless, 1.

In twenty-two out of twenty-nine cases, or seventy-six per cent., chronic glomerular nephritis was responsible for the improper elimination. In striking contrast to this figure uremia was attributable to acute glomerular nephritis in only one instance.

Considering the fact that the Long Island College Hospital maintains an acute medical service, the low incidence of acute nephritis is surprising. A few acute nephropathies were studied, but in only one case of acute glomerular nephritis did the blood urea nitrogen approach 50 mgms. to the 100 c. c. Chloremia appears to be the rule here. When this group was placed upon a fixed chloride diet and the output was measured by Volhard's method, a definite chloride retention could be demonstrated.

Antecedent infections and intoxication.—Tonsillitis, 7; scarlet fever, 7; syphilis, 3; rheumatism, 2; bichloride poisoning, 2; empyema, 1; pulmonary tuberculosis, 1; malaria, 1; diphtheria, 1; gout, 1.

Only those antecedent infections and intoxications which bore an apparent relationship with the onset of uremia were included in this tabulation. Scarlatina and tonsillitis stand first in importance. Recurrent attacks of tonsillitis seemed to be the last straw. Possibly each infection caused an acute focal glomerular nephritis without symptoms. When the safety limit of destruction of renal units was passed, waste products began to accumulate in the blood.

SYMPTOMATOLOGY.

Frequency with which various symptoms occurred:

Drowsiness	22
Coma	18
Vomiting	18
Edema	14
Restlessness	12
Dyspnea	12
Headache	11
Increased tendon reflexes	11
Twitchings	7
Emaciation	7
Nycturia	6
Cough	6
Amaurosis	5
Polyuria	5
Epistaxis	5
Hiccough	5
Vertigo	5
Ascites	4
Diarrhea	4
Anuria	3
Precordial pain	3
Convulsions just before death	3
Delirium	3
Petechial hemorrhages	2
Itching	2
Epigastric pain	2
Hematemesis	1
Pain in limbs	1
Chills	1
Backache	1
Tetany	1

It is noteworthy that the symptoms standing highest in frequency are, with the exception of edema and dyspnea, those observed in experimental animals and in cases of total ablation of renal function. The essential symptoms of uremia, therefore, are increasing drowsiness gradually merging into coma, vomiting, restlessness, headache, increased tendon reflexes, and muscular twitchings. The numerical importance of edema and dyspnea is probably exaggerated by concurrent cardiac decompensation in a certain percentage of cases.

Edema was present in fourteen patients. It was directly attributable to a lesion of the convoluted tubules in seven instances (six cases of the mixed type, chronic glomerular nephritis plus nephrosis and one of nephrosis); to myocardial insufficiency three times; and once to acute glomerular nephritis. Therefore it appears that edema is merely an inconstant concomitant of uremia, due, when present, to associated tubular degeneration or cardiac incompetence.

The low frequency of convulsions is in striking contrast to the importance so commonly attached to them. In all three instances the convulsions did not appear until immediately before death, and they were apparently due to asphyxia of the brain.

URINARY FINDINGS

Albuminuria	28
Cylindruria	18
Red blood cells in urine	10
Complete anuria	1
Hyposthenuria	12 out of 16 cases

BLOOD FINDINGS

Red blood cell count in twenty-seven cases.

1,500,000-2,000,000	1
2,000,000-2,500,000	1
2,500,000-3,000,000	1
3,000,000-3,500,000	3
3,500,000-4,000,000	5
4,000,000-4,500,000	8
4,500,000-5,000,000	6
5,000,000-5,500,000	2

The average red blood cell count was 3,750,000.

Hemoglobin (Sahli's method) in twenty-five cases.

20 per cent.-30 per cent.	1
30 per cent.-40 per cent.	1
40 per cent.-50 per cent.	0
50 per cent.-60 per cent.	3
60 per cent.-70 per cent.	7
70 per cent.-80 per cent.	11
80 per cent.-90 per cent.	2

The average hemoglobin was sixty-three per cent. Sahli. The average color index was 0.84.

In no case did the color index reach as high as one. In some of these cases the red blood cell volume was determined. The findings did not run parallel with the cell count and the hemoglobin. Therefore, it would appear that the red blood cell count is not a reliable index to the degree of hydremia.

WASSERMANN REACTION.

Positive	3
Negative	20
Not reported	6

These findings would indicate that the retained nitrogenous products of uremia do not give rise to false positive Wassermann reactions. One of the positive cases was complicated by general paresis. The urea nitrogen in the three positive cases was 60, 75, and 150 mgms., respectively, which findings lead us to believe that retained nitrogen does not interfere materially with the reaction.

EYE SIGNS.

Papilledema with vascular degeneration	8
Albuminuric retinits with vascular degeneration	7
Retinal hemorrhages with vascular degeneration	5
Vascular degeneration uncomplicated	3
Stiff pupils	2
Petechial hemorrhages over scleræ	1
Exophthalmos	1
Ptosis of upper lid	1

CARDIOVASCULAR CHANGES

Cardiovascular changes investigated were cardiac hypertrophy, blood pressure, and arteriosclerosis.

The evidences upon which judgment as to cardiac hypertrophy was based were physical examination, x rays, and postmortem examination. The figures indicate that in thirty-eight per cent. of cases the hypertrophy was not determined clinically. It is thus apparent that absence of hypertrophy does not exclude uremia.

Cardiac hypertrophy present	18
Cardiac hypertrophy absent	9
Cardiac hypertrophy doubtful	2

BLOOD PRESSURE:

Systolic.		*Diastolic.*		PULSE PRESSURE:	
75-100	1	50- 75	1	20- 30	2
100-125	2	75-100	12	30- 40	1
125-150	6	100-125	3	40- 50	6
150-175	7	125-150	9	50- 60	5
175-200	9	150-175	4	60- 70	7
200-225	1			70- 80	2
225-250	3			80- 90	4
				90-100	1
				100-110	1

Average systolic blood pressure 168. (This average was markedly reduced by one case complicated with chronic pulmonary tuberculosis, one with cardiac decompensation, and two with bichloride poisoning.)

Average diastolic blood pressure 108.

Average pulse pressure sixty.

Arteriosclerosis was definitely observed in eight cases.

COMPLICATIONS.

Myocardial insufficiency	3
Perforation of uterus with pelvic peritonitis	1
Bronchopneumonia	1
Cerebral thrombosis	1
Lobar pneumonia	1
Mitral insufficiency	1
General paresis	1
Gangrenous stomatitis	1
Pulmonary tuberculosis	1
Otitis media	1

OUTCOME.

Died in hospital	25
Discharged unimproved	3
Discharged improved	1

Retention of urea nitrogen in the case that showed improvement never rose higher than fifty mgms. to the 100 c. c. and the creatinin was normal. The man was a sailor and has not been heard from since he left the hospital.

These figures demonstrate the importance of distinguishing chemical uremia as an entity in so far as prognosis is concerned. In the retention group the outlook is practically hopeless. As an index to the severity of the case, the blood chemical analysis is much more trustworthy than the clinical picture.

SUMMARY

All of the cases of nephropathy occurring in the wards of the Long Island College Hospital were studied according to a fixed scheme, laying particular stress upon the blood chemical analyses. From this group there were separated all those cases which showed a urea nitrogen of fifty mgms. to the 100 c. c. or more. I believe that the term uremia should be strictly limited to this category of nitrogenous retention due to renal inadequacy.

As regards blood chemistry, urea nitrogen was found to furnish the most reliable index to the progress of the case and to bear the greatest prognostic value. Increases to figures of 300 mgms. per 100 c. c. invariably portended death in a few days. Uric acid was very variable, and, while always increased, maintained no ratio with the urea nitrogen. Creatinin tended to rise in the same proportion with the urea nitrogen.

The study of etiological factors would indicate that heredity, sex, and occupation are not important predisposing causes. As to age twelve of the twenty-nine cases appeared in the third decade. The most important underlying renal condition responsible for uremia is chronic glomerular nephritis, being present in twenty-two instances. Acute glomerular nephritis was accountable for only one case of uremia. Tonsillitis and scarlatina were the most frequent antecedent infections.

The symptomatology revealed a surprising similarity to nephrectomized animals and to instances of total deprivation of renal function in man. Drowsiness gradually merging into coma, vomiting, edema, dyspnea, increased tendon reflexes, restlessness, and headache stood highest in frequency. Concurrent cardiac decompensation is undoubtedly responsible for the edema and dyspnea in many instances. Eclamptic evidences were infrequent. Convulsions occurred only three times and always just before death. The urine showed evidence of nephropathy in every case.

A moderate grade of secondary anemia was present in the majority of cases. The average red blood cell count was 3,750,000; the average hemoglobin, sixty-three per cent.; the average color index, 0.84. The Wassermann reaction was positive in only three out of twenty-three patients.

Cardiac hypertrophy was positively determined in eighteen cases; arteriosclerosis, in eight. The average systolic blood pressure was 168; diastolic, 108; pulse pressure, sixty.

Myocardial insufficiency was the most important complication. It was directly responsible for death in three cases.

The author's references will appear in his reprints.

The Standard Treatment for Malaria

By C. C. BASS, M.D.,
New Orleans, La.

The standard treatment for malaria recommended by the National Malaria Committee is, "For the acute attack ten grains of quinine sulphate by mouth three times a day for a period of at least three or four days, to be followed by ten grains every night before retiring for a period of eight weeks. For infected persons not having acute symptoms at the time only the eight weeks' treatment is required." It will be noted that there are two parts of the treatment, the first to relieve the clinical symptoms and the second to cure the infection. In the present paper the effectiveness of the first part of the treatment for the purpose of relieving the clinical symptoms will be discussed.

Fever or chills and fever are the most constant clinical symptoms of malaria. They are definite symptoms. Fever is measurable and susceptible of statement in definite terms of temperature. Although other symptoms may also be present, they are not recognizable or demonstrable in all cases. It often occurs that a person may have a few malarial parasites in his blood without having any recognized symptoms due to the infection. However, if his resistance gets low enough to allow the parasites to multiply sufficiently to produce any clinical symptoms and an active case of malaria develops, he is certain to have fever, if not chills and fever. These being the most prominent and constant clinical symptoms, they serve as a reliable guide as to the effect of treatment. Any treatment that relieves them relieves any other symptoms of active malaria that may be present.

There is a general impression and belief that although quinine relieves these symptoms in most cases, there are some in which fever or chills and fever persist for days and sometimes for weeks in spite of full quinine treatment. Such opinions are unfortunately expressed or supported by many of the prominent authorities on malaria.

It often happens that in supposed cases of malaria unnecessarily large amounts of quinine are given in one form or another over considerable periods of time in an effort to break the fever, much to the detriment of the patient. In such cases the diagnosis was usually incorrect, and the patient either did not have malaria at all or, if malaria was present, there was some other coexisting disease or condition responsible for continuation of the symptoms. Malaria played no part in their production.

During the past six years fortunate circumstances have brought me into contact, direct or indirect, with the treatment of a great many people for malaria. The effectiveness of the standard treatment in relieving the clinical symptoms has been kept constantly in mind and special search has been made for cases in which it failed. Many cases in which this has been reported have been investigated. Up to the present time not a single case has been found in which fever or chills and fever due to malaria have continued for four days when the patient was taking as much as thirty grains of quinine daily.

During the past year a further effort has been made to find these socalled resistant cases of malaria by keeping in touch with the cases of malaria in the large hospitals of New Orleans through the kind assistance of interested medical students. The date on which the patient began taking quinine and the amount taken were recorded. Any case in which the patient was given as much as thirty grains of quinine daily and in which the temperature rose above normal on or after the third day was reported to me for personal investigation. Thus far four cases have required investigation.

In one of these, tertian parasites had been found and confirmed by me just three days previously. Thirty grains quinine sulphate had been given daily for four days and the patient now had a temperature of 104° F. Investigation revealed some delirium, rose spots on the abdomen, gurgling in the right iliac fossa, tympanitis, positive Widal, and typhoid bacilli grew in the blood culture. This was a case of malaria and typhoid. There were no malaria parasites found at this time. The typhoid was the cause of the fever.

In two other cases it was found upon investigation that the nurse had recorded the quinine as being given, depending upon the orderly to give it. One patient had actually received one dose of ten grains and the other two at the time of investigation of the supposed failure of the treatment. They were given thirty grains of quinine daily and the temperature did not rise above normal in either of these cases at any time after the first twenty-four hours during which they actually received the quinine.

The fourth case was one in which the diagnosis was made by the laboratory man on one doubtful parasite found on one of the many blood examinations made. The patient continued to have irregular chills and fever for several weeks, although she was given as much as fifty or sixty grains of quinine daily for several days at a time. The chills and fever finally stopped without a diagnosis being made. It was not malaria.

During this period of six years, when the question of the effectiveness of the standard treatment has been kept constantly in mind and resistant cases have been sought, I have been unable to find a single case in which the clinical symptoms were not entirely controlled within a period of four days by as much as thirty grains of quinine daily. So far as I have been able to ascertain, no such case has occurred in the large hospitals of New Orleans during the past year, during which time they have especially been sought here.

Although I am not prepared to say that such exceptional cases do not occur, they are at least so rare that I have not been able to find even one case. Therefore, so far as my own experience and observations go, the standard treatment is one hundred per cent. effective in controlling the clinical symptoms of malaria.

Retinitis Associated with Disease of the Cardiovascular System*

By WILLIAM L. BENEDICT, M.D.,
Rochester, Minnesota,
Section on Ophthalmology, Mayo Clinic.

In 1892 Gunn presented to the Ophthalmological Society of the United Kingdom a patient with changes in the retinal arteries which he said were identical with those seen in a case of chronic albuminuria exhibited at the same session of this society. He referred particularly to four features of vascular change: 1, the sharpness and distinctness of the central light streak; 2, the color of the whole surface of the vessel which is lighter than normal; 3, a metallic appearance resembling bright copper wire, and, 4, impeding of circulation in the retinal vein, wherever an artery or even a small twig passes over it. This appearance Gunn considers an evidence of high arterial tension. He believed that the metallic, copperlike appearance of the vessels, noted with the ophthalmoscope, was caused by hyaline degeneration of the arterial walls, and he reports that it had been observed in many cases of chronic albuminuria, and in several cases in which no albumin was found, but in which the high arterial tension suggested the probability of changes in the arteries, similar to those usually associated with chronic renal disease.

In a paper before the same society in 1898, Gunn described "uncertain ophthalmoscopic changes . . . dependent primarily on an affection of the retinal arteries," and gave his opinion that, "such visible primary changes in retinal arteries are commonly, if not constantly, a part of a similar, more general, and therefore more important change in small arteries elsewhere." These ophthalmoscopic changes in the retinal arteries described by Gunn and attributed by him to certain causes on clinical grounds and on the pathological findings of Gull and Sutton, constitute the visible contributory factors of the picture said to be typical of ophthalmoscopic findings in cerebrospinal arteriosclerosis, in general arteriosclerosis, and in nephritis associated with increased arterial tension. So far as the description of the retinal arteries is concerned, it might apply as well to the retinitis of diabetes. The retinitis that is associated with any constitutional disorder may show one or more of the arterial changes here described, as indeed chronic vascular disease is a common occurrence, found even rather early in life, but is more common in persons of advancing age, and in those who have suffered from chronic intoxications. Other factors that make up the syndrome, such as hemorrhages, exudate, edema, and their sequelæ, are of secondary importance in their significance, are often the direct result of the vascular changes, and are merely corroborative details of the picture, which point to additional sources of disorder, and direct attention to concurrent organic disease. Even the absence of visible arterial changes in a retina that contains a number of hemorrhages and areas of exudate is a finding of the first importance in considering the relation of the retinitis to any disease in a diagnostic or prognostic sense, and whatever other changes are found must be grouped about the normal appearance of the arteries, just as much as if arterial changes were present. It may be assumed that the capillaries take some part in producing the appearance of the fundus in such conditions as are brought about, or accompanied by frank vascular disease, whether it be primary or secondary, but unfortunately the capillaries are not visible, as such, by any means we have at hand for adequate examination of the living eye, and microscopic examination has not contributed information which would indicate that any important rôle is enacted in the capillary area. The precapillary bed composed of the visible arterioles in the retina is available for study under magnification of about fifteen diameters, an advantage not gained elsewhere in the body, and has the further advantage of being quite similar in every respect to the precapillary bed in the central nervous system, and is not exposed to outside influences as are the vessels of the conjunctiva or other mucous membranes, or of the nail bed in the fingers. There is little evidence to be found, either by clinical examination or microscopic study, that the retinal veins play any important part in the production of the changes seen in the fundus in diseases of the cardiovascular renal system, and the changes that are produced in the veins themselves are apparently secondary to change in the artery, the heart, or the chemical constituents of the blood.

I am not unmindful of the difference of opinion expressed by pathologists as to what properly constitutes arteriosclerosis and the manner in which pathological changes are produced, but for our purpose all changes which lead to thickening of the wall of the artery, or hypertrophy of any of its coats, may be classed as arteriosclerosis. The reason for the inclusion of all varieties of arterial thickening becomes apparent when we consider the end stages of any given process, and the frequency with which the various factors responsible for the changes act at the same time. Marchand includes in arteriosclerosis all those changes of the arteries which lead to a thickening of the wall, particularly of the intima, in whose development degenerative changes (fatty degeneration with its results) sclerosis and calcification (including calcification of the media) arise, together with inflammatory and productive changes (15).

ETIOLOGY.

Sclerosis of the retinal arteries may safely be said to arise from three main sources, primary atheroma, hyperpiesia, and toxemia and inflammation. Disease of the kidneys as a cause of retinal arteriosclerosis is of secondary importance, for although nephritis is often indicated by the ophthalmoscopic picture, its part in producing retinitis is to fill in details around the vascular system of the retina, and is probably additive rather than causative. In a discussion on this subject in January of last year I made the statement that "the most prominent factor in the production of retinitis of diseases of the vascular system and of nephritis is sclerosis of the retinal arteries, to which are added other features characteristic of the etiologic factor of the sclerosis, and a careful analysis of the ophthalmoscopic picture presented may indicate the type of constitutional disorder back of it all, and give important information with regard to its severity and course."

---

*Read before the Buffalo Academy of Medicine, November 29, 1922.

ATHEROMA.

When one reviews the original communications of Gunn on the ophthalmoscopic evidence of general arterial disease, and the many articles on the subject, that have since appeared in the literature, it seems strange that no definite attempt has been made to follow the clue given by the ophthalmoscope to the changes in the arteries, and to trace back through the vascular system the course of events that has led up to those changes. While many observers have called attention to the various stages of vessel change, they have added little to the original description of those changes by Gunn, and so far as I know the occurrence of those changes in essential hypertension has not been brought out, but has been considered a part of the syndrome of advanced cardiovascular disease. I wish particularly to call attention to the group of cases to which we refer as essential hypertension in persons who have no evidence of nephritis, except occasional albuminuria.

Attention has been directed to the copper color of the distended arteries, to the central light streak reflex and to the fine white lines along the course of the arteries in advanced cases, all of which were mentioned by Gunn in his original communication. Statistical records of retinal changes have been compiled with the findings in the urine, blood, and blood pressure in persons presenting evidence of nephritis and cerebral sclerosis, but the character of the changes in the retinal vessels has not been differentiated, nor has the sequence of other organic changes been noted. No doubt this is largely due to the questionable significance of high blood pressure and the conservatism of physicians and pathologists, but it seems that sufficient data are now obtainable to warrant a differentiation of cases of high blood pressure, and to set apart the cases of primary sclerosis from those in which sclerosis is secondary to hypertension, basing the diagnosis and prognosis on the appearance of the retinal vessels.

Textbooks do not point out the retinal changes characteristic of early hypertension with late sclerosis, and these conditions are not distinguished from the mixed symptoms which characterize the late stages of involutional degeneration, toxic vasculitis, and hyperpiesia. No statistics are available from which to estimate the relative incidence of the involutional degenerative type of sclerosis. Several studies, however, have been made from which it can be concluded that nephritis is not a necessary complication, and that increased blood pressure is not present as a rule. Furthermore, as Barker says, "the time seems to have come when the significance of sclerosis of the arterioles must be sharply discriminated from that of sclerosis of the rest of the arterial system. And when one uses the term, arteriosclerosis, he should, to avoid confusion, make clear in each instance the part of the arterial system to which he is applying the term."

As I have said in a previous paper, the sclerosis of involutional degeneration is not the same as that of the degeneration that follows hyperpiesia and both forms may differ from the sclerosis brought about by the perivasculitis of syphilis, lead poisoning and other chronic intoxication. The ophthalmoscopic picture is not always clear, and opinions of various observers may differ in cases which are not well-marked, but a sufficient number of cases may be differentiated to make the attempt well worth while because of the aid given the clinician in his attempt to reach a definite diagnosis.

ARTERIOSCLEROTIC RETINITIS.

The retinitis of primary arteriosclerosis, when uncomplicated, is characterized by arteriovenous compression, contracted arteries whose calibre is not materially decreased, pipestem sheathing, arterial plaques, beading, increase in the light reflex stripe, and silver wire arteries. There are hemorrhages in the nerve fibre layer, proliferation of new vessels, arterial injection of the nerve head, giving it a brick red color, and extreme tortuosity and increase in the number of the arterial twigs in the region of the macula. Small areas of capillaries are deprived of blood supply, giving rise to ischemia and white spots. Only rarely is edema present.

These evidences of arteriosclerotic retinitis are not present at all times and all stages of the process. With the ophthalmoscopic findings just described, and low blood pressure, cerebral arteriosclerosis and an absence of systemic sclerosis would be suspected; on the other hand, with high blood pressure, the presence of systemic sclerosis also would be suspected. The sclerosis of the arteries, giving rise to these symptoms of arteriosclerotic retinitis, has its origin in atherosclerosis, but sometimes follows toxic endarteritis, known as secondary arteriosclerosis. Most commonly, however, the atherosclerosis is acting alone and with a comparatively low blood pressure, but when increased blood pressure is added, evidences of nephritis may appear with retinal signs characteristic of a renal break. The arteriosclerosis of the atheromatous type is, as far as we know, a primary disease of the arteries, and is not dependent on inflammation of any particular organ, or on toxemias. It is the most common type of arteriosclerosis found among the insane, and often results in apoplexy, or other disturbances of the central nervous system.

In a recent article by Woltman it is said that the average blood pressure of 64.4 per cent. of patients with cerebrospinal arteriosclerosis observed by him was 130 mm. systolic and 78 mm. diastolic. The highest pressure noted in his series was 260 mm. systolic and 150 mm. diastolic. He says that practically normal blood pressures are shown in patients with arteriosclerosis of the nervous system.

HYPERPIESIA AND MALIGNANT HYPERTENSION.

That increased arterial tension may produce changes in the retinal vessels, indicative of its presence, was suggested by Gunn in his first communication from which I have quoted. The association of increased arterial tension with cardiovascular and renal disease is so common that it is not as yet fully accepted that a person may have long continued hypertension without some nephritis, particularly if the diastolic blood pressure maintains a high level. It has also been questioned whether hypertension can produce arteriosclerosis independent of other causes, and so far as I know we are not yet in a position positively to conclude that such is the case. It would seem, however, to be well established that the degree of hypertension is independent of the degree of peripheral arteriosclerosis, and of the amount of kidney damage present in a single case, and the evidence is becoming more abundant and more conclusive that increased arterial tension does produce a change in the walls of the arteries which, for the present at least, may be considered arteriosclerosis, and that the organic changes which are found in the vessels of the retina are produced by this tension. Ritchie describes the progress of the disease as follows: "In its earliest stages essential hypertension is not associated with any structural vascular change, but as the disease progresses, a diffuse arteriosclerosis of the smaller arteries and especially of the arterioles makes its appearance. The high pressure becomes inveterate, the larger vessels eventually become affected and the heart is found to be hypertrophied."

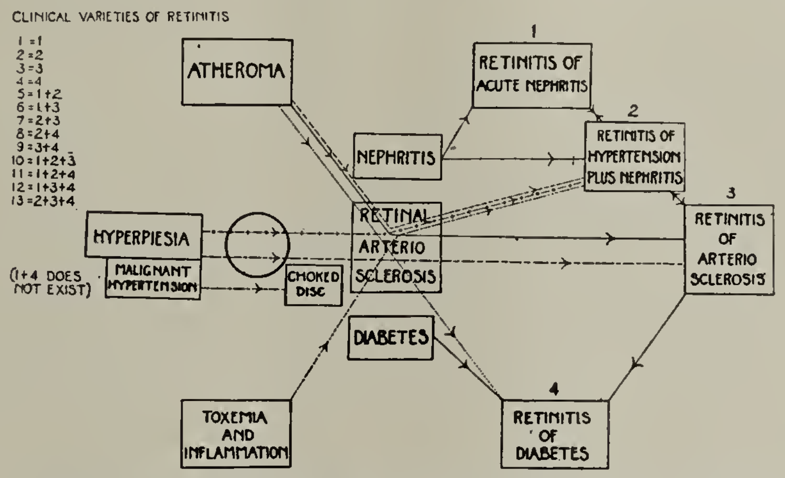

FIG. 1.—Diagram showing division of clinical varieties of retinitis associated with arteriosclerosis. The circle indicates the relative position of the retinal condition in which can be recognized evidences of increased arterial tension.

In discussing the causes underlying high blood pressure Barker says, "It seems to me very certain that sclerosis of the arterial system, other than that involving the minute arterioles at the precapillary barrier, has but little, if anything, to do with the production of high blood pressure. And there is some reason to believe, also, that even the sclerosis of the arterioles of small organs may be secondary to high blood pressure, or to what causes it, rather than that the increase in blood pressure is the result of arteriolar sclerosis. Once a high blood pressure has been maintained for a time and arteriolar sclerosis has begun, a vicious circle may be formed, the arterial hypertension favoring the progress of arteriolar sclerosis, and, the arteriolar sclerosis helping to maintain, to increase, and to 'set' the arterial hypertension." Wherever there is a multiplicity of causes working toward a given end, the task of sifting them out and according each its proper place and sequence is difficult. Arterial hypertension is caused by, or is associated with, a great variety of physical and chemical processes, some of which can be detected and their force measured, while others are believed to be active although evidence of their existence is lacking in the majority of instances.

Foster says, "there are two main factors in operation in producing elevation in blood pressure of all types. The factors are, first, increased peripheral resistance dependent on vasoconstriction induced primarily through the central nervous system. The second factor is increased heart output. . . . When the systolic and diastolic pressure are both elevated, we have a combination of two factors, increased heart output and a narrowing of the peripheral field of circulation due to vasomotor influences."

The hypertension that comes with nephritis has been ascribed to various toxic substances which are presumed to act directly on the epithelium of the kidney, on the vascular endothelium, and on the retina; and to toxic substances that normally are eliminated by the kidney, but which, under circumstances that lead to lowered functional activity in the kidney, are retained in the blood stream, resulting either directly or indirectly in a change in the fundus. When this retention of toxic substances, which are usually estimated in terms of nitrogen, is associated with rise of blood pressure, the condition is created which by the French is termed azotemia, and according to the views of Rochon-Duvigneaud is directly responsible for the inflammatory changes in the retina in albuminuric retinitis. This explanation is emphatically denied by Schiech and Volhard, who ascribe the changes to the rise of blood pressure alone. That toxic substances from other sources also give rise to increased arterial tension is shown by "an accumulation of experimental evidence on the influence of certain nitrogenous products of decomposition in raising blood pressure. Dixon and Taylor, in 1907, found an extract of placental tissue an active principle that caused a rise in blood pressure due to contraction of arterioles. Rosenheim, in 1909, showed that the pressor effect was due to P - hydroxyphenylethylamine. About the same time Barger and Dale, in 1909, showed that this substance was the chief body concerned in the pressor effect that could be obtained from an extract of putrid meat. It is derived from tyrosine by anaerobic disintegration. Several other amines which exert a pressor influence have been described by Barger and Dale, 1910. It has been shown by Dale and Dixon, 1909, that some, at least, of these amines can be absorbed from the alimentary canal and produce pressor effects when so administered. The possibility of these pressor substances arising by means other than bacterial action has been shown by Emerson, 1902, who found a pressor substance in the autolysis of pancreas under conditions that excluded putrefaction, and by Langstein, 1902, who obtained the same body in prolonged peptic digestion of egg albumen. The results of these investigations show that certain amines which exert a pressor influence may originate in the intestine and be absorbed to the blood stream. They also suggest the possibility of certain nitrogenous substances with a pressor influence arising in the tissues as a result of perverted or incomplete metabolism of protein."

Endocrine disorders are common among persons with arterial hypertension, but what the relations of these disorders of the thyroid, hypophysis, suprarenals, and gonads to hypertension are, if there be any, remains to be determined. Barker concludes that, 1, high blood pressure appears to depend chiefly on a narrowing of the lumina of the arterioles in the precapillary areas; 2, the arteriolar narrowing is at first functional, due to hypertonus of the arteriolar musculature, though later it is also partly organic, due to arteriolar sclerosis, and, 3, the different types of chronic arterial hypertension would seem to be closely related to one another, probably representing different stages in the development of one and the same fundamental process, a process that may, however advance with variable rapidity and with variable associated involvements of cardiovascular, renal, cerebral and other structures in different cases. A marked arterial hypertension probably does not continue long without becoming complicated by structural changes in the various organs of the body, most often the heart, kidneys, and central nervous system. The damage to the kidneys, however, is often small in severe cases of hypertension. Just what part the kidneys play in a case of malignant hypertension is sometimes difficult to estimate, but the low blood urea findings would hardly support the theory that nitrogenous products are responsible for the changes seen in the retina.

Of twenty-five unselected cases of malignant hypertension in the Mayo Clinic, edema of the optic nerve was seen in nine, ranging from one diopter to seven diopters. The appearance of the disc in the early stages of the change, was characteristic of intracranial pressure, and did not show changes characteristic of nephritis until after signs were found in the urine and blood. The average systolic pressure was 230 mm., the average diastolic 141 mm., the phenolsulphonephthalein excretion was good (the lowest on admission was twenty per cent. in two hours and fifteen minutes) and the blood urea was below 50 mg. for each 100 c. c. Symptoms which could be attributed to the hypertension had been present for as long as seven years, the average was two years, and the shortest period was six weeks. I will not consider malignant hypertension at this time, but merely direct attention to the possibility of great changes occurring in the fundus, with grave prognosis, in patients whose kidney function is good and whose blood analysis gives no reason for apprehension. Hardy advises against decompression for the relief of the papilledema. Experiments conducted by Hunter, Gilbert, and Hewlett showed that animals die only when very large doses of urea are given, and the high blood urea of persons suffering from intestinal obstruction, who never show changes in the eye grounds, lends doubt to the theory that retention of nitrogen is responsible for the retinal changes.

Hypertension may exist for years without giving rise to thickening of the arterial walls, that is detectable by palpating the radial or brachial vessels. The early arteriosclerotic changes are to be found in the arterioles of the retina and are quite visible with the ophthalmoscope. Ritchie says, "From the involutionary type of arteriosclerosis it differs in site, character, extent, progress and prognosis; from chronic interstitial nephritis it differs, largely in prognosis, symptomatology and mode of termination. But while drawing these distinctions between involutionary arteriosclerosis and essential hypertension and between essential hypertension and chronic Bright's disease, I would add that there are many cases in which involutionary disease becomes engrafted on hypertensive arteriosclerosis, and many cases of the latter in which the terminal stages present more or less unequivocal indications of superimposed chronic renal disorder, while in most, if not in all, longstanding cases, arteriosclerotic changes occur in the kidneys, though the characteristic symptoms of chronic interstitial nephritis are absent."

There is a type of vascular disease that must be mentioned in considering arteriosclerosis, and this is the end result of chronic endarteritis from infections such as syphilis, tuberculosis, and intermittent infections. The metastatic infection that results from foci of infection around the teeth and tonsils probably acts in two ways: directly on the vessel walls (embolism of the vasovasorum) and indirectly through disease of the kidneys and heart. The differentiation of the activities of toxemia and inflammation must be largely academic, inasmuch as hypertension is so common in the resulting diseases, but the two conditions must be set aside in order that essential hypertension as a factor in the production of arteriosclerosis will stand out more clearly. In the presence of vascular degeneration, Nature attempts to repair the damaged vessel and a thickened and changed wall results.

Pathological studies of the early vascular changes occurring in sclerosis of the retinal arteries are difficult to secure for the obvious reason that suitable eyes are seldom available. Furthermore, there are technical difficulties that must be overcome in the preparation of the material for study. The late stages of arteriosclerosis are well known and easily recognized; but the early change, which is so often brought first to the oculist, and which must be studied clinically by the physician, merits closer attention.

As I have mentioned, the basic ophthalmoscopic picture in diseases of the cardiovascular system is the structural appearance of the arteries. I have described this appearance in reference to the main groups of the disease.

In the sclerosis of hypertension, the proliferation of the intima seldom amounts to complete occlusion of the lumen of the vessel as it often does in the atheromatous type of sclerosis. The thickening of the walls because of hypertrophy outside the lamina elastica gives the tubelike appearance to the artery and accounts for the straightening of the bends. There is more elasticity to an artery so thickened than there is to one of the atheromatous type, which accounts for the difference in the angle of the arteriovenous crossing. Proliferation of new vessels, characteristic of atherosclerosis, comes as a result of the closing off of the lumen of the artery, and widening of smaller arterioles and capillaries until they carry sufficient blood for nourishment of the parts of the retina impoverished by the shutting off of the regular source of supply. So, too, one sees few or no ischemic areas in the fundus in the early sclerosis of hypertension, the visual function is not seriously impaired as far as can be seen in the visual fields, and entire occlusion of the arterioles with formation of new arteries is very seldom seen. Furthermore, the white plaques around the second and third divisions of the arteries and in the retina around the region of the disc and macula are not a part of this picture except in late stages in which the sclerosis has become far advanced.

The retinal signs of hypertension sclerosis in the order of their appearance may be divided into two stages: 1, narrowing of the arterial reflex stripe and increased tortuosity of the arteries, loss of transparency of the walls of the arteries, giving a copper color, and indentation of the veins which are crossed closely by arteries, and, 2, noticeable contraction of the arteries both in diameter and length (straightening out of curves and bends), deep indentation of the veins of small arterioles, due to their contraction, appearance of minute white spots in the fundus scattered around the macular region without any particular reference to arterial endings, and veins two or three times the diameter of the corresponding artery, and showing ampullaform dilatation distal to the arteriovenous crossing.

This constitutes the picture that is seen in persons who have progressive hypertension before any clinical or laboratory evidence of nephritis is found; these symptoms may continue for many years without noticeable change in renal function, or, as has been stated by Gull and Sutton, with "kidneys healthy, whilst heart much hypertrophied and minute arteries and capillaries much thickened by 'hyalin-fibroid' substance."

To the picture of retinal vascular fibrosis may be added other changes that indicate the effect of renal disease; but the retinitis that occurs with insufficiency of renal activity gives no indication of the duration of diseases of the kidneys before the onset of retinitis. Insufficiency of renal action or retention of nitrogenous products, although results of nephritis, probably do not in themselves produce the retinal changes. Just how much of the retinal picture results from vascular changes and how much from retention of nitrogen is not known. Indeed, in some cases it would seem that the vascular disorders alone produce the retinitis, while in others the products of retention seem to act in the absence of vascular changes producing a retinitis characteristic of nephritis. Acute nephritis may occur in a person who has had essential hypertension for years and be independent of the cause or effect of that hypertension, and may produce a retinitis of acute nephritis, even as in a person whose retinas had previously been free from vascular change. The retinitis would be produced just as in a person whose blood pressure is not habitually elevated, although its course will be altered by chronic hypertension. More particularly is this true of persons whose arteries have become sclerosed through long continued hypertension. "To the arteriosclerosis of hyperpiesia, the kidneys, so far as is yet known, stand in no correlation; except that generally speaking, the kidney is one of the organs whose arteries are affected early."

It is a common clinical experience that persons who are subject to high blood pressure are prone to have attacks of nephritis against which their resistance is poor. Because of the difficulty in making a satisfactory diagnosis of nephritis, it is often difficult to decide whether a given patient is suffering from essential hypertension or hypertension with nephritis. Curiously enough, the retinal arteries may show well advanced fibrosis resulting from hypertension, and yet retinitis of nephritis be absent in cases in which laboratory findings and clinical signs may indicate the presence of chronic nephritis. It is well known, however, that a severe break in renal function in a person who has hypertension will produce marked changes in the fundus, characteristic of acute nephritis, in addition to the vascular fibrosis. The picture is a composite one. The earliest noticeable additional changes consist of edema and hyperemia of the disc and flame-shaped or lanceolate hemorrhages in the retina near the disc. Following these, edema of the retina and areas of soft cotton wool exudate appear. If the blood pressure suddenly becomes greatly elevated, as usually happens with a break in renal function, the hemorrhages, edema, and exudate will be correspondingly increased.

The chemical changes that occur in the fluids of the eye during the progress of the disease of the kidney and other conditions that lead to, or are associated with, arterial hypertension have been suggested as a fruitful field of investigation, and it is probable that with carefully observed and controlled cases such a study would throw some light on the nature and cause of the exudates and hemorrhages to be found in the retina, the cause of vitreous degeneration and of opacities in the lens. To carry out such studies satisfactorily requires good laboratory facilities and frequent tests which require technical skill, besides observation of patients under circumstances that will allow full control of fluid intake and food.

Focal infection is known to play an important part in the production of organic disease, particularly of the kidney, and its relationship to hypertension must be considered. Just what part focal infection plays in primary sclerosis of the vascular system has yet to be worked out, but it is quite certain that patients under treatment for vascular disease improve after infected areas have been eradicated.

A great deal can be accomplished by treating patients who have early hypertension before the vessels are materially thickened, or the kidneys or heart severely damaged. After considerable change has taken place in the retina, the evidences of arteriosclerosis and of retinitis may almost entirely disappear if the general condition can be improved and the blood pressure kept down. Compensated hypertension in a person of middle age may be carried for years without any sign of sclerosis appearing in the fundus, but that is an exceptional case. When sclerosis appears, it usually marks the beginning of secondary or complicating diseases, and unless the tension is lowered, the sclerosis lowers the resistance to disease. It is important that the early signs be detected and interpreted, and I know of no better means than that afforded by repeated examination of the fundus with the ophthalmoscope.

Subacute Bacterial Endocarditis*

By JOSEPH BARSKY, M. D.,
New York,
Attending Physician to Beth Israel Hospital.

The presentation of a paper on the diagnosis and clinical course of subacute bacterial endocarditis with reports of cases from Beth Israel Hospital needs no apology. So rarely are these cases recognized that not a single one has been reported under this heading to the Bureau of Records within the past ten years. The Board of Health records give 4,839 deaths caused by either acute or chronic endocarditis in the same period, and 217 cases with the endocarditis as a contributary cause of death. This is, therefore, in itself good reason for presenting this paper with the prime purpose of bringing to your attention a class of cases which is not as rare as is commonly believed.

I would like to emphasize the importance of recognizing these cases from the prognostic viewpoint. While they almost all appear mild and innocent at the onset, the termination is quite different, death being the rule. The physician seeing such a case at the onset is much too prone to give a good prognosis and promise a speedy recovery, but the contrary is the truth. Such optimism on the part of a physician is never forgiven nor forgotten by the friends or relatives of the patient. That we may guard ourselves against such optimism is one of the reasons for this paper.

I shall endeavor briefly to describe the more common symptoms of this disease as they are usually encountered in the majority of cases in private practice, as well as in the hospital. I shall also point out the difficulties (and they are unquestionably many) which interfere with the recognition of this malady.

The symptomatology as described in this paper is based upon a study of thirty-eight cases in the wards of Beth Israel Hospital and twelve cases seen in my private practice. I wish to state at the very outset that the salient features herein described relate to my series of cases only, and that not every case presents all the symptoms. Nor can it be said that the symptoms enumerated are the only ones which may be present. I am giving only those observed by me and from the records of these cases.

DEFINITION.

Subacute bacterial endocarditis is a chronic progressive generalized bacteriemia, lasting usually from two months to as many years and terminating, as a rule, fatally.

CAUSATIVE AGENT.

The causative agent is, in ninety-five per cent. of the cases, the Streptococcus anhemolyticus. It usually localizes upon rheumatic, sclerotic or syphilitic valves, and occasionally in healthy hearts. In this series, four patients had normal hearts.

MODE OF INVASION.

The mode of invasion of the organism is as varied as is the symptomatology. This organism is found in all infected teeth, tonsils, sinuses, and occasionally in the intestinal tract. Any or all of these sites serve as the gateway for entrance into the body at any time that the resistance of the individual is lowered, from any cause whatsoever. The original point of infection is not, as a rule, found, and this will exclude all cases wherein the focus of infection is evident, such as puerperal sepsis, which may be caused by the same organism.

INCIDENCE.

Male, fourteen; female, twenty-four. The youngest on record in my series is one year, a case previously reported by Dr. Francis Huber (1). This case presented all the typical signs and symptoms of the disease. With the possible exception of a case reported by Dr. Coutley, my own is, as far as I know, the youngest on record. The oldest was aged sixty-five.

PATHOLOGY.

The gross pathological findings are quite distinctive. If the patient lives long enough, there are infarcts and minute bacterial emboli in most of the organs, such as kidney, spleen, lungs and brain. There are firm yellowish or greenish vegetations on the line of closure of the mitral valve extending into the auricles and the chordæ tendineæ. Occasionally the aortic valves are involved. Ulceration is rare, The Streptococcus anhemolyticus could be cultivated from the vegetations in many cases.

There are several theories given to account for the selective localization of the bacteria. Mechanical considerations point to an interesting possibility—that the beating of the valves traps the bacteria from the blood streams and drives them into the tissue. Thus the bacteria become entangled and produce the lesion. Chemical damage to the valve may assist the process. Another theory, revived by Rosenow, is that the bacteria come to the valve as emboli by way of capillary bloodvessels. However, according to Coen and Langer, the heart valves contain no capillaries except at the base. Rosenow bases this argument upon the experimental production of bacterial endocarditis by the injection of streptococci into the blood stream. This experiment, however, sheds no light upon the cause of the selective localization of the bacteria. Personally, I am inclined to favor the mechanical theory.

SYMPTOMATOLOGY.

The most important feature in the diagnosis is a good, careful history, which necessitates close attention to all the complaints of the patient, no matter how trivial they may seem.

The onset of this disease, whether upon a previously healthy heart, or upon a rheumatic, sclerotic or syphilitic valve, is, as a rule, insidious. The patient does not realize that he has been sick for any length of time. Indeed, in a number of cases, the onset is so gradual that the patient cannot fix a definite time for the beginning of his illness. Upon close and careful questioning we may bring out the fact that a feeling of fatigue was more marked than usual after an ordinary day's work. Occasional chilly sensations and irritability were experienced by some, and the patient thought that he was suffering from grippe. Indeed, physicians often diagnose such cases as grippe, put the patient to bed, and in a few days allow him to go about his daily tasks. So gradual and insidious is the onset that patients go about for weeks and months unaware that they are suffering from this most treacherous and, as a rule, fatal disease, for sooner or later, with but a few exceptions, all succumb.

---

*Paper read before the Eastern Medical Society, October 14, 1921.

Pain, in some part of the body, is mentioned by some observers as the first complaint. I have had two or three cases in which the chief complaint was pain. One case presented severe pain in the knee joints, and was unable to support the body in an erect posture. The second patient complained of pain in the right thigh and was so sensitive to pressure that she would cry out at the slightest touch. The pain suggested the possibility of a periostitis. In both these cases I was able to elicit a history of trauma which had occurred a long time ago, and was almost forgotten by the patient. The best explanation that I can offer for the pain in these cases is that the trauma has lessened the resistance of those particular structures which, therefore, were hypersensitive in their reaction to the toxic substances circulating in the blood. Furthermore, there was the possibility of an actual lesion in these cases, such as a periostitis in one and a fibromyositis in the other.

Dizziness is another presenting symptom which is not rare. I remember the case of a boy aged sixteen who awoke in the middle of the night and became so dizzy that he could not find his way back to bed unassisted. When I saw him the following morning, he was more or less dazed, and could not give a good account of himself. He was removed to the Beth Israel Hospital where subsequently a typical case of subacute bacterial endocarditis developed. The boy had no history of previous illness, had neither cardiac signs nor a history which would lead us to suspect such a condition. Subsequently there developed a mitral systolic, slight cardiac enlargement to the left (probably due to dilatation), petechiæ and positive blood culture. This patient made a good recovery.

Fatigue, irregular temperature, profuse sweating, irritability, anorexia, moderate loss of weight, and facial pallor may be the only symptoms even if the case is far advanced, and no other symptoms may ever appear until the termination. In the greater number of cases there appears sooner or later a distinct chill and a decided rise in temperature. The temperature, usually preceded by a chill, may rise suddenly as high as 104°, with a daily swing of three to four or even five degrees and may continue thus for weeks or months. Then it may come down to a lower level, such as 101° to 102°, with a daily swing of only one to two degrees, and remain at this level for months. We had one case, a girl of twenty, a congenital cardiac patient, in whom there developed subacute bacterial endocarditis. At times her temperature would make a daily swing of from six to eight degrees, especially after intravenous injections of colloidal salts. A violent chill always preceded the rise in temperature. I do not know how long she had been ill before her admission to the hospital, where she remained for nine months. Her constant sense of wellbeing was an outstanding feature. As soon as her chill subsided, she would ask to be allowed out of bed. She did not complain of any pain. She had typical signs with positive blood culture and autopsy findings.

I remember two patients, one of whom had a normal temperature for seven weeks, the other a normal temperature for three weeks, just before death. In the second case the entire illness was known to last fourteen months. Previous to the onset the patient had a normal heart. Not only was her temperature normal for three weeks, but the pulse was of good quality, 80 to 90 and perfectly regular. It remained regular until but a few minutes before death, when it became flickering and irregular. She had a few twitchings in the facial muscles. Before the onset of these symptoms she was in a semicomatose condition for a short time. Then with their onset she went into complete coma, and died within half an hour. Forty-eight hours previously she had had good hopes of recovery, though it was evident that dissolution was near. In her case the blood cultures were repeatedly negative.

As a rule the temperature is what may be termed regularly irregular; there is no typical curve. This in itself is an aid in diagnosis. Sweating is a very common symptom and occurs in a great proportion of cases. I have seen cases where the patients were literally drenched. I would consider the profuse perspiration which occurs even when the temperature is not very high as a prominent symptom. However, in the late epidemic of influenza I have witnessed such profuse perspiration. It also occurs in severe malarial infections and in cases of acute malignant endocarditis.

I should like to emphasize the fact that in the absence of other definite causes for such reactions as a continuous temperature, irregular in type for any length of time, chilly sensations, or distinct chills and drenching perspiration, weakness, and peculiar pallor, the possibility of subacute bacterial endocarditis should at once suggest itself. I have seen cases that showed no symptom other than those mentioned terminate fatally within six to eight months.

I particularly remember one patient who always had a sense of wellbeing. He thought his inability to work was due to the hemiplegia. Even this improved so that the patient was able to help himself considerably. He had an infection of Streptococcus anhemolyticus with a positive blood culture of more than two hundred colonies to the plate. He showed no petechiæ or other signs which we commonly associate with subacute bacterial endocarditis. Pallor, sweating, and irregular temperature were the only symptoms present. Later there developed a left sided hemiplegia which, of course, could have occured in any case of valvular disease and of itself could not be considered as a symptom of subacute bacterial endocarditis. He had no skin manifestations of any kind. His appetite was good, he slept fairly well and had a sense of wellbeing during his entire stay at the hospital. He left the hospital and died two weeks later. His main symptoms were continuous rise in temperature of an irregular type, rare chilly sensations, weakness, moderate loss of weight, drenching sweats, peculiar pallor of the face with an intensification of the pallor at the nasolabial folds. Later his spleen became palpable and he occasionally complained of pain in that region. This was probably due to infarcts.

The other signs which may be considered pathognomonic are the cutaneous phenomena, though, as I have stated above, a goodly number of cases do not present any other symptoms or signs than those I have just enumerated. These cutaneous manifestations are not essential in making a diagnosis, but if we do find them, then we are surely dealing with a case of subacute bacterial endocarditis, even if the blood culture be negative. Indeed, they are so important that it requires a good deal of courage to suggest this diagnosis in their absence. One of my cases illustrates this point very well. A man of thirty with a previously damaged valve began to experience fatigue, chilly sensations, and progressive weakness. He called in his physician, who considered it a grippal infection. After remaining in bed for a while without improvement, he was sent to a hospital for observation and seen by one of our best men, a man very familiar with this disease. The case was diagnosed by him as subacute bacterial endocarditis. The patient's condition, however, improved within a short time. The blood cultures being negative and since the temperature became normal, to all appearances he seemed well. After two weeks stay in the hospital he was sent home, his diagnosis being changed at the time of discharge. After being home for about a week he was suddenly seized with a distinct chill. When I saw him later, he had all the cutaneous phenomena, pathognomomic of this disease. As a rule these skin lesions are not very easily detected. We must look for them very carefully.

Of prime importance are the petechiæ, which are embolic in nature and not hemorrhagic. They are mostly found upon the mucous membrane of the mouth and upon the conjunctivæ. Since their description and the method of detection as given by Dr. Libman is, to my mind, the best, I quote from his lecture on subacute bacterial endocarditis as follows:

"It is important when looking for petechiæ to examine particularly the conjunctival mucous membrane of the upper and lower lids, the supraclavicular and the lateral cervical regions, the buccal membrane, and the fundus of the eye. When the lesions are found in the conjunctiva, concerning the petechial nature of which one is in doubt, it is a good plan to squeeze the lid at its margin, just as one presses on the skin to determine whether a lesion is petechial or not. If the particular conjunctival lesion is a petechia, it will stand out sharply against the anemic conjunctival mucosa. In looking for petechiæ on the buccal mucous membrane one must be careful not to mistake traumatic lesions for embolic petechiæ. One must be particularly cautious in deciding about lesions of the buccal mucosa near the labial commisures, because many people have a tendency to bite the mucous membrane and produce small hemorrhages.

". . . Petechiæ with white centres are the most vital in diagnosis, because then one can have no doubt that the lesion is an embolic one, and not a symptom of a purpuric nature. It is especially important (and this holds especially true for the conjunctival lesions) to note whether the central white part is elevated or not, because such elevation does not occur in subacute streptococcus endocarditis. Petechiæ with elevated white centres are pathognomonic of infection by staphylococci and usually by the Staphylococcus aureus. They are really miliary abscesses surrounded by a zone of hemorrhage."

Next in importance are the subcutaneous hemorrhages. These are found in most cases of septic infection arising from any cause. It should be noted here that in the final analysis we are dealing with a septicemia, caused by a peculiar organism called by some observers Streptococcus viridans and by Dr. Libman Streptococcus anhemolyticus. This organism, for some reason unknown at present, has the property of localizing upon a damaged heart valve or other parts of the endocardium. Occasionally the organism attacks a healthy endocardium, and from this central point the bacteria as well as their toxins are distributed to all parts of the body and produce symptoms which are common to all bacterial invasions. Hence we must expect to find certain phenomena which are common to all toxemias. The purpuras are one of these common signs.

Erythematous rashes of all varieties are common. I have seen cases resembling erythema nodosum. In subacute bacterial endocarditis, the individual lesions are not as large or as painful, nor is the infiltration of the skin as deep or as longstanding as the lesion in erythema nodosum. In subacute bacterial endocarditis the lesions come and go, are small in size, and are distributed over all parts of the body, usually upon the extremities. In one instance they were present upon the face, and in some cases patches were also present upon the finger pulp. These patches are usually bright red and painful, but never so painful as in erythema nodosum. When the circulation is poor, they assume a purplish tinge. There are other skin manifestations distributed over various parts of the body; these can be classed under the general heading of erythema multiforme.

TENDER NODES—OSLER'S SIGN.

Their history dates back to 1853, and they have been observed by many others since, but little attention was paid to them until Osler's paper appeared. These lesions are commonly known as tender nodes. Dr. Libman found them in about fifty per cent. of his cases. Osler's description is as follows: ". . . . They appear at intervals as small swollen areas the size of a petechia, at others as large as one and a half cm. in diameter. They are raised, red, with a whitish spot in the centre. They may pass away in a few hours, but usually last a day or longer. Their most common site is upon the tips of the fingers, which may be slightly swollen. They also occur in the pads of the fingers and toes, upon the thenar and hypothenar eminences, sides of the fingers and the skin of the lower part of the arm. In one case they occurred in the skin of the flanks.

They are never hemorrhagic. Sometimes they are of a vivid pink hue with a slightly opaque centre."

I personally have seen very few of them in my cases. Perhaps in the earlier days we did not look for them so closely, but in our later cases they were most carefully watched for by the entire staff and by Dr. Levine, our dermatologist, but we have seldom succeeded in finding them.

The face has a peculiar pallor. Peculiar is the best description that I can offer. It is not the pallor one observes in cases of secondary anemia. The pallor of subacute bacterial endocarditis is present in cases of only mild anemia; once it has been seen, the impression remains with the observer.

Cough is usually present, but it is the result of several factors, and not the result of the subacute bacterial endocarditis *per se*. Among the factors causing the cough may be mentioned pulmonary engorgement as a result of mitral stenosis or of cardiac insufficiency. The causative factor may be a complicating chronic bronchitis, which may be present even though there be a fair heart muscle. In the absence of any recognizable cardiac or pulmonary signs, the cough may be occasioned by the toxic substances circulating in the blood, or possibly by the enlarged tracheobronchial glands. The respiratory rate is governed by the same factors as mentioned and also by the temperature. Given a mild toxemia, fair heart muscle, and a slight elevation of temperature, the respiratory rate is but slightly increased. Of course, in the presence of complications such as pulmonary embolism, infarct or pneumonia, we shall have other symptoms referable to this complication.

ABDOMINAL PAIN.

Abdominal pain or referred pain is common. The pain is mostly due to infarcts of the spleen or kidneys or to small infarcts in the mesentery. The occurrence of the infarcts is followed by pain which is referred to the abdomen from the affected organ. There may also be small hemorrhages into other abdominal viscera which may cause pain. Epigastric pain may be present in other cardiac conditions, and is probably due to liver engorgement.

Diarrhea is found in a small number of cases and is exhausting. Anorexia, nausea and vomiting are present as the gastrointestinal manifestations of the toxemia or cardiac insufficiency. The spleen is, as a rule, palpable and painful, and at times greatly enlarged. Cases are reported in which an original diagnosis of Banti's disease was made. One of my patients, a woman, came to the Beth Israel Hospital for observation. She had a moderate temperature, an enlarged spleen and an old endocarditis. She caused rather a considerable discussion as to the etiology of the splenic enlargement. I suggested the possibility of subacute bacterial endocarditis. Her blood culture was negative. The Wassermann was, however, positive. Later a facial palsy developed. The clinical picture of an enlarged spleen, facial palsy, fever and a positive Wassermann, as well as her improvement under specific therapy, was all in favor of lues. To my mind she seemed a case of subacute bacterial endocarditis, although all I had to sustain my opinion was the clinical impression. This patient left the hospital apparently cured of the condition for which she entered, only to return eight months later in a semicomatose state. She died soon after. The blood cultures and the autopsy findings proved the case to be one of subacute bacterial endocarditis as well as of luetic infection.

Pain over the splenic area and in the costovertebral angles is due to infarcts, and we can often elicit tenderness in these areas upon deep pressure. In examining any patient, the spleen and kidneys should be carefully palpated, as tenderness and pain in these areas are of diagnostic import.

Pain in various parts of the body is generally complained of by some patients, and this is undoubtedly due to the toxic substances affecting the neuromuscular endings. It is probable that we may have a mild form of a peripheral neuritis, or a neuromyositis, for moderate pressure over the muscles will, in some patients, cause pain. Pain in the joints and over the long bones may also be present. In none of my cases was there a distinct swelling of a joint. Pain over the lower part of the sternum, Dr. Libman's sign, was present in a few cases only. One case that I had in mind I saw with another physician. The history given was that of progressive weakness, irregular temperature, profuse perspiration and complete anorexia. She presented the peculiar pallor, an old cardiac lesion, and pain at the lower part of the sternum. I ventured a diagnosis of subacute bacterial endocarditis, which later proved to be correct. The reason for the pain at the lower part of the sternum is not clear at present. Whatever explanation the future may offer, at present we must content ourselves with the fact that the pain is present in some cases and that it is a valuable sign.

The diagnostic signs afforded by the examination of the heart depend upon the previous condition of that organ. In cases without any previous endocardial damage we may not discover any adventitious cardiac sounds. In one case which had a stormy onset, a severe course, in which the patient eventually recovered, I found, early, a soft blowing mitral systolic murmur with an enlargement to the left. The enlargement was probably due to dilatation. In a second case, which ran a moderately severe course and where the patient recovered after about four months' stay in the hospital, there developed, much later in the disease, a mitral systolic murmur. He still has this murmur, but is otherwise well, although slightly neurotic. The patient had a positive blood culture.

The examination of the heart itself does not throw light upon the diagnosis of the disease. The cardiac condition is not especially marked until late in the course. The aggravation may be either mechanical or due to the exhaustion as a result of the toxemia. All other phenomena are vascular, such as embolisms and infarcts in various parts of the body. Embolic aneurysm may also occur, although I have not seen it, but a number of cases have been reported in the literature. One very interesting case with autopsy findings was reported by Dr. Libman. Embolic complications are more common in this disease than in any other, and should be looked for carefully, as they furnish valuable information.

A whole chapter could be written upon the symptomatology produced by the emboli and infarcts, but neither time nor space permit. The symptoms of these complications depend upon their location. The spleen, brain, and kidneys are the common sites of choice, but any other part of the body may be affected. Traces of blood, faint traces of albumin and casts are usually found in the urine, due to infarction of the kidneys, but I do not remember seeing a true nephritis. Edema may be present, depending upon cardiac efficiency. I have on record a case in which edema was present, although the heart seemed to be in good condition, as far as could be determined by physical and instrumental examinations. In this case the renal efficiency was good, as shown by the phenolphthalein tests and by blood chemistry. Effusion into the various serous cavities may be present, and there also may be cardiac decompensation with little or no edema. Edemas in cardiac diseases require more lucidation. No adequate explanation has as yet been given as to why in some cases of cardiac decompensation we may have general anasarca, in other cases we may have effusion into the serous cavities, in still other cases effusion into one pleural cavity only, and in a fourth class we may have liver enlargement only with but little edema.

The pulse is, as a rule, regular, if the previous cardiac condition was such as not to impair its regularity. It may, as we would expect, be somewhat increased in rate, depending upon the temperature and toxemia.

The physical examination of the cardiovascular system, including the use of the electrocardiograph and pulse tracings, does not offer any further diagnostic data.

The genitourinary system is, as a rule, involved, due to congestion of the kidneys from the cardiac asthenia and from the effect of the toxemia and infarcts. In the latter event we have a greater or less amount of blood in the urine, pain in the renal area radiating along the course of the ureter of the affected side toward the bladder.

LABORATORY FINDINGS.

Laboratory findings do not assist us in the diagnosis of these cases unless it be a positive blood culture of Streptococcus anhemolyticus.

Blood examination may give us from a mild secondary anemia to a severe form, presenting from 3,000,000 red cells and fifty per cent. hemoglobin to about 1,500,000 red cells and thirty per cent. hemoglobin. Our lowest leucocyte count was 5,000; our highest 48,000. This latter was of a patient who had a negative blood culture, but who was clinically a case of subacute bacterial endocarditis. The differential counts did not present any distinctive features.

The urine examination showed from faint traces of albumin to definite traces of albumin with a small number of casts. The urine also showed from a moderate amount of blood to grossly bloody urine. We had one case in the hospital in which the patient passed almost pure blood and clots for about three or four days. She had excruciating pain with tenesmus. Only a short time prior to this complication the functional activity of her kidneys was fair. The blood chemistry was not remarkable.

THE COURSE OF SUBACUTE BACTERIAL ENDOCARDITIS.

This disease may run a course which lasts anywhere from two months to two years. The longest duration amongst my series was fourteen months, the shortest about three weeks. The prolonged case presents a most varied symptomatology. The onset may be very severe, with chills, high temperature, profuse perspiration, exhaustion, a marked secondary anemia, pallor and infarcts of the spleen, kidneys or brain. Other cases may show nothing except a slight continous temperature, a palpable spleen and if the patient is not of a chronic valvular type a physical examination may show only a faint mitral systolic murmur with possible slight enlargement to the left.

This disease may last for months and as the patient becomes bacteria free, the temperature may subside. Both patient and physician are then lulled into a sense of security at having passed through the dangers safely with the port of rest and recovery in sight. Soon this feeling is rudely destroyed and another voyage is begun which practically always continues into the sea of the great unknown. In my series, I have had two recoveries of undoubted cases of subacute bacterial endocarditis.

As the disease progresses to its fatal termination, the patient becomes weaker and the exhaustion is profound. The marked asthenia is a result of both the anemia and the toxemia. Anorexia is complete, the patient refusing all food and vomiting when forced to eat. Apathy or drowsiness may be followed by a semistuporous condition or complete coma. The pulse becomes weaker, small, irregular and hardly perceptible. The respirations assume the Cheyne-Stoke's type although the temperature may be normal, the patient expires with symptoms resembling either cerebral insult or renal insufficiency. This mode of exodus is not the rule. Nature is more merciful and brings in some form of intercurrent infection, usually a pneumonia which is terminal. If this does not occur, death ensues as a result of embolism or infarct in a vital part of the body, thus bringing down the final curtain upon one of the most distressing scenes which the practitioner is called upon to witness.

DIFFERENTIAL DIAGNOSIS.

The first prerequisite for making a diagnosis of the disease under consideration is to bear in mind the possibility of this illness in all cases of prolonged fever, irregular in type, progressive weakness, mild anemia, pallor of the face, chilly sensations, palpable spleen, profuse perspiration, and periods of improvement which may last for a shorter or longer period, especially in cases where there are signs of chronic endocarditis. The symptoms given above and pain in the different parts of the body, especially at the lower part of the sternum, should at once make us suspect subacute bacterial endocarditis. A blood culture should be taken and of course if positive no other disease need be considered, but if negative we should consider all the causes of prolonged fever.

SUBACUTE RHEUMATISM WITH FEVER.

Subacute rheumatism with fever and valvular involvement will give us much concern and will offer the greatest difficulty. In this connection it must be borne in mind that no hard and fast rule can be laid down for the differentiation of these two diseases. They are both unquestionably of bacterial origin. Their symptomatology may not differ in many cases and the difference between the two diseases is rather of degree than of kind. At times the differentiation is impossible until late in their course. The prognosis in the two cases is vastly different and of utmost importance from the viewpoint of the ultimate result as well as of diagnostic skill. In subacute bacterial endocarditis the prognosis is generally fatal, but in subacute rheumatism the prognosis is good as far as immediate recovery is concerned. In differentiating these two diseases we must rely upon a careful history and centre our attention especially on the mode of onset and later on the complications. In subacute rheumatism with fever we have a history of a very acute onset with high fever at times, though very seldom, preceded by a chill, great prostration and symptoms of an acute arthritis either simultaneously involving several large joints or single joints following one after the other with the usual symptoms, such as swelling, redness, severe pain on moving the joint, and increased heat. The indirect evidence may be that we either find a pericarditis or a history of severe pain over the precordium. Effusion into the pleural cavity is not rare. The pericarditis and the pleural effusion may be considered either as a complication or a part of the rheumatic infection. The spleen is not palpable in subacute rheumatism, neither is the peculiar pallor present.

In subacute bacterial endocarditis the onset is gradual, the patient cannot give a definite time for the beginning of the illness and although he may complain of pain in some part of the body, and even in the joints, nevertheless the signs and symptoms of an acute arthritis are lacking. Nor does pericarditis or the pleural effusion form any part of the subacute bacterial endocarditis unless it be as a sequence to some complication. In a word, in subacute bacterial endocarditis the onset is gradual, the spleen is always palpable, the peculiar pallor is always present, the skin manifestations are of an embolic nature, and in a good many cases pain is present over the lower part of the sternum.

TYPHOID FEVER.

In considering the cases of prolonged fevers, typhoid, especially the relapsing type, will suggest itself as a first possibility. In fact, if our case of subacute bacterial endocarditis occurs in a patient free from previous endocardial involvement, the chances are that our first diagnosis will be typhoid. We shall have great difficulty in ruling it out for the onset in both classes of cases may be similar.

The symptoms, such as progressive weakness, loss of weight, secondary anemia, asthenia, prolonged fever of an irregular type and a palpable spleen, all of which are common to all bacterial infections, are also common to both diseases. A few points, however, may help us to differentiate the two. We must rely upon our laboratory findings a great deal. In typhoid we always have a leucopenia, complement fixation and Widal positive, typhoid bacilli in the blood, if early in the disease, and in the urine and feces later in its course.

Abdominal symptoms, complications and sequelæ are quite different in typhoid. The skin manifestations, if present, are unlike those seen in subacute bacterial endocarditis. The peculiar pallor is absent. Vascular changes are rare in typhoid but are a part of the evolution of subacute bacterial endocarditis. Lastly, endocardial symptoms are present only rarely in typhoid but are always present in subacute bacterial endocarditis.

TUBERCULOSIS.

To rule out tuberculosis anywhere in the body will indeed be difficult in such cases of suspected subacute bacterial endocarditis with no skin manifestations, negative blood culture and only presenting symptoms of irregular temperature, sweats, secondary anemia, progressive weakness and loss of weight. Surely from these symptoms alone a diagnosis of tuberculosis will naturally suggest itself, and the only way that I know to rule this out is by a thorough, painstaking, oft repeated physical examination. Examination of sputa and urine for tubercle bacilli and animal inoculation, a thorough x ray study of the chest, and possibly a complement fixation for the organism may aid us. The autourine test of Wildbolz for active tuberculosis should also be utilized.

HODGKIN'S DISEASE.

Hodgkin's disease involving the retroperitoneal glands and showing a moderate fever, mild secondary anemia, progressive weakness, and abdominal pains with gastric symptoms such as nausea and vomiting will certainly offer great difficulty in making a differential diagnosis. Nevertheless, in Hodgkin's disease a close study of the pains in the abdomen will disclose that they do not have the characteristics of the pains in subacute bacterial endocarditis, since in the latter disease the pains usually originate in the spleen or kidney (due to infarcts), come suddenly and disappear slowly. The pains have their characteristic radiation towards the bladder (if originating in the kidneys) and they usually subside after the acute onset and may reappear whenever there are fresh infarcts. In Hodgkin's disease with involvement of the retroperitoneal glands the pain is constant, there is pain in the back as well, the radiation being totally different. Lastly. in Hodgkin's disease, the pain will seldom remain confined to one group. There is, as a rule, a leucopenia and at times a slight increase in the eosinophiles. Jaundice, ascites and swelling of the lower limbs (not due to circulatory disturbances but to pressure) may be present.

PYELITIS.

Pyelitis will come in for a good share of the discussion, especially when it is remembered that in subacute bacterial endocarditis we have renal symptoms such as pain, urgency, frequency, blood, albumin and a few casts in the urine due to infarcts. Moreover the two conditions may coexist. The differentiation here is more than an academic question. In pyelitis, most commonly due to calculus, we may save our patient by timely intervention, whereas in the presence of subacute bacterial endocarditis we are helpless in most instances. All modern methods employed in the study of impaired renal function should be utilized, namely, cystoscopy, x ray with ureteral catheters *in situ,* collargol injection and x ray for kidney outline and calculus. Separate functional tests for renal excretion, culture of the urine, animal inoculation and blood chemistry should also be done. Lastly, if after all our efforts we are still in doubt, I personally am in favor of surgical intervention if the patient's general condition permits. We have nothing to lose, and if our suspicions are confirmed we may save our patient's life.

SPLENIC ANEMIA.

Only the beginning or the first stages of splenic anemia need be considered here, for in its later development we have a distinct clinical picture which is very unlike subacute bacterial endocarditis. In the beginning, the only symptoms that we may encounter that are common to both diseases are splenic enlargement and moderate fever. In splenic anemia, the leucopenia is an outstanding feature, the white cells numbering as low as one to three thousand, with a relative lymphocytosis. As a rule, there is no anemia at the outset. Hemorrhages from the esophagus and other parts may be present. A totally different picture presents itself in subacute bacterial endocarditis. Malaria of the irregular type I mention as a possibility. It can easily be ruled out by a blood examination for the plasmodia. Such examinations should be repeatedly done.

In closing, I should like to mention cases of meningococcus septicemia without meningeal involvement until late in the disease. Such cases have been reported by Dr. H. J. Morgan, of Johns Hopkins. These cases run a course similar to subacute bacterial endocarditis. In the cases of meningococcus septicemia reported, blood culture was always positive for the meningococcus.

The following cases have been chosen from my service at Beth Israel Hospital, as representing fairly typical examples of the course of the disease.

CASE I.—R. D., female, aged twenty-five. Admitted to Beth Israel Hospital January 19, 1915.

Family history—Father had socalled rheumatism, otherwise negative.

Previous history—Married eight years, four pregnancies, three stillbirths, one child died in infancy, deserted by husband three years ago, frequent attacks of precordial distress, palpitation and dyspnea since age of fifteen; typhoid at sixteen; pneumonia three years ago, frequent colds.

Present illness—Confined to bed for last four months with weakness, frequent attacks of palpitation, headaches, dizziness, nausea, vomiting, and severe productive cough. Seven days ago there suddenly developed fever, chill, sweats, paroxysmal cough, dyspnea and pain in right chest; appetite lost.

Physical examination—Fairly well nourished young woman, prostrated, markedly dyspneic and cyanotic. Sibilant and sonorous râles throughout the lungs. Apex beat was felt in fourth interspace four and one half inches; to left of midsternal line. The first sound was followed by a short systolic murmur transmitted to the axilla. There was a rough loud systolic murmur at the base, heard all over the precordium and transmitted into the vessels of the neck. The abdomen was slightly distended, liver felt at costal margin, spleen and kidneys were not palpable. Slight pretibial edema, clubbing and cyanosis of finger tips. Reflexes normal.

Laboratory—Urine (fifty-seven examinations), specific gravity 1.015-1.030; dark amber; acid, albumin, faint trace; no casts; few red and white blood cells; guaiac positive at last few examinations. Blood (twenty-five examinations), red blood cells, 5,200,000-3,300,000; hemoglobin, 80-60 per cent.; white blood cells, 5,200-12,400; polymorphonuclear, 66-81 per cent.; mononuclear, 34-19 per cent. Wassermann negative, Widal negative, eye culture negative, urine culture negative, nose and throat cultures negative; blood culture, first seven negative; eighth, Streptococcus viridans. X ray, left pleural effusion; heart considerably enlarged. Marked evidence of periostitis of bones of elbow joint.

Course—During the nine months that intervened between this patient's admission to the hospital and her death, she ran a septic temperature between 98° and 104° except for a period of six weeks later in her illness, when it was practically flat. She had many crops of petechiæ, urticarial wheals, and severe attacks of dyspnea following injections of colloidal salts; attacks of pain in the splenic and lumber regions; occasional hemoptyses; transient edemas, and large collections of purpuric spots. Frequent chills and constant loss of weight. Towards death her temperature was frequently subnormal, reaching as low as 93° and 94° F.

CASE II.—J. S., male, aged twenty-five. Admitted to Beth Israel Hospital September 7, 1915.

Family history—Negative.

Previous history—Scarlet fever; typhoid; gonorrhea three years ago; no rheumatism, no tonsillitis, no cardiac symptoms. Had always been well.

Present illness—Onset gradual six days before admission with lumbar pain and sore throat. He was in hospital for two days, and left feeling well; next day had mild chill followed by profuse perspiration. Return of lumbar pain, temperature markedly elevated. No headache or epistaxis.

Physical examination—Well developed and nourished, no dyspnea or cyanosis, throat slightly congested, left tonsil enlarged, lungs clear; heart, no enlargement to percussion, no thrills or murmurs, sounds of fair quality. Abdomen, no palpable viscera, no pathological reflexes, extremities negative.

Course—Ran a septic temperature 98-99° in the morning, rising to 104° in the evening for a period of eight weeks. Pulse relatively slow. Shortly after admission an occasional localized systolic murmur was heard at the apex; this later became permanent and was transmitted. Dull pain in left lumbar region, spleen felt two fingers below costal margin. There were no petechiæ at any time. The temperature gradually fell and patient was discharged eleven weeks after admission.

I am indebted to Dr. Solon S. Bernstein for his aid in the preparation of this paper.

Hypertension with Especial Reference to Prognosis

By JOSEPHUS TUCKER ULLOM, M.D.,
Philadelphia, Pa.

With the advent of the blood pressure apparatus, the medical profession has looked at an old disease from a new angle and has been able to measure the pressure in the arterial system more accurately. Before the introduction of the sphygmomanometer, reliance was placed on the palpating finger and the stethoscope; and there was the high tension pulse and the accentuated or ringing aortic sound, but a standard for comparison was lacking, and as must always be the case without an instrument of precision, there were inaccuracy and confusion.

For about fifteen years the sphygmomanometer has been in common use and an enormous number of observations have been made. The profession has acquired experience with the instrument and has been able to draw some conclusions from that experience. From the nature of the condition, its insidious onset and symptomless course, observations on the blood pressure over a long period are desirable. It would be interesting to watch the course of the disease from its inception to its close. This is occasionally possible, but not often, as there is usually considerable hypertension before it is discovered. Once discovered, the question arises as to prognosis. With the dissemination of knowledge relative to high blood pressure among the laity, there has arisen a feeling that the person who has such a condition is speedily doomed and it is but natural that he should exhibit great curiosity as to the prognosis in his individual case. Scarcely a day goes by that the practitioner is not asked about the chances for life of some one whose blood pressure is above normal. With the idea that an analysis of an experience of twelve years might throw light on the question of prognosis and enable one to answer more intelligently questions in regard to it, this survey was undertaken.

Our present conception of hypertension is that it is, first, a manifestation of kidney disease; second, a manifestation of arteriosclerosis pure and simple without kidney involvement, or third, a manifestation of some disturbance or imbalance caused by the menopause. There may be a mixture of groups one and two and there may be other causes of hypertension but as all the patients except one in this series fell into the first three groups, discussion will be confined to them. In this series, any reading over 160 mm. systolic was considered pathological and when the readings varied from time to time an average was taken. Those patients were placed in the nephritic group who persistently showed albumin and casts and diminution of phthalein excretion. Those were placed in the arteriosclerotic or essential hypertension group who showed no albumin or faint traces or only occasional casts and no diminution in phthalein excretion.

Those were placed in the menopausal group who showed rise in blood pressure about the age of forty-five with no albumin or casts or diminution in phthalein excretion.

This series comprised 112 patients who were under observation for periods ranging from a few months to twelve years. In the series of 112 patients, fifty-one were of the nephritic group, and fifty-four were of the vascular group, while six were placed in the menopausal group. One was probably due to thyroid disturbance.

Of the 112 patients, thirty-eight or about one third are dead. Of those who died twenty-nine, or 76.3 per cent. were in the nephritic group and only nine or twenty-three per cent. were in the arteriosclerotic group. None of the menopausal patients have died. Of those living, twenty-two, or thirty per cent. are in the nephritic group; forty-five, or sixty per cent. are in the arteriosclerotic group; six, or eight per cent. are in the menopausal group.

In the nephritic group there are twenty-four men and twenty-seven women. Of the twenty-nine dead, seventeen were men and twelve were women; about seventy per cent. of the men and forty-four per cent. of the women. In the arteriosclerotic group there were fourteen men and forty women. Of this group nine are dead; three of whom were men and six were women, twenty-one per cent. and fifteen per cent. respectively. Fifty-seven per cent. of the nephritic group are dead, forty per cent. at the end of two years.

These figures show clearly that the greatest mortality is in the nephritic group and they also show that essential hypertension is much more common among women than men. This is probably due to a climacteric origin of hypertension in women.

In the nephritic group, those who died were under observation on an average of 2.3 years. Those who died in the vascular group were under observation on an average of 2.8 years. Those living in the nephritic group have been under observation on an average of three years. Those living in the vascular group have been under observation on an average of 3.7 years.

The cause of death, taken as a whole, was apoplexy in fifteen, or forty per cent.; heart disease in sixteen, or forty-two per cent.; uremia in three, or 7.9 per cent.; angina pectoris in two, or 4.25 per cent. and carcinoma in two, or 4.25 per cent. Several patients in this series had angina but did not die of it.

A consideration of the death rate in those showing a systolic blood pressure over 200 mm., gives twenty-four dead out of fifty-four, a percentage of forty-four. Those showing 200 and below were fifty-eight, with thirteen dead, a percentage of twenty-two. With approximately equal numbers in each group the mortality in those above 200 is double that below 200.

A consideration of the patients in the series showing a diastolic pressure over 100 mm. gives fifty-four with twenty-seven dead, a percentage of fifty. Those under 100 give fifty-eight with twelve dead, a percentage of twenty.

A consideration of the ages of the patients shows that the average age of the nephritic group was fifty-eight, the average age of the vascular group was sixty-six. Taking the ages by decades and grouping two patients below forty with the forty to fifty decade, we find in the first group twenty patients with eight deaths; the mortality being forty per cent. Between fifty and sixty there were twenty-five patients with nine deaths, a mortality of 34.6 per cent. Between sixty and seventy there were thirty-five patients with nine deaths, a mortality of 25.7 per cent. Between seventy and eighty there were twenty-one patients with eight deaths, a mortality of forty per cent. Over eighty there were five patients with three deaths, a mortality of sixty per cent. It would seem that these figures give a curve with two peaks, one occurring between forty and sixty, and the other occurring after seventy. This may be more apparent than real. Transient paralyses were found in twenty-four cases of the series, a percentage of 21.4. Fifteen or sixty-two per cent. are dead.

From a consideration of the facts set forth the following conclusions are reached:

1. The cause of hypertension in men is usually chronic renal disease. In women hypertension due to vascular disease is more frequent. This is probably due to a menopausal origin of the condition in women.

2. The prognosis is much more grave in hypertension due to renal disease than it is in that due to vascular disorder.

3. The cause of death is generally cardiac failure and apoplexy in about equal numbers.

4. Blood pressure of over 200 mm. is of grave significance, the mortality above 200 being double that below. A diastolic pressure of over 100 is an even more serious manifestation.

Some Points in the Examination of the Heart for Life Insurance*

By FREDERICK W. PRICE, M. D., F. R. S., Edin.,
London,
Physician to the National Hospital for Diseases of the Heart; Senior Physician to the Royal Northern Hospital, London.

(*Concluded from page 618*)

An apical presystolic or diastolic thrill, indicative of mitral stenosis, must be carefully distinguished from mere vibration of the chest wall which may be occasioned by a forcibly acting heart when the ribs are rigid; in the latter case, by separating the fingers and placing them in the intercostal spaces the osseous vibrations are not felt.

Lastly, I would especially emphasize the great importance of percussing accurately the left border of deep cardiac impairment in cases in which the apex beat is faint or absent. For I have seen many cases in which enlargement of the heart, associated with myocardial degeneration, was not detected because of an omission in this respect. A combination of the existence of subjective symptoms during or after physical exertion, evidences of enlargement of the heart, and an absence of physical signs indicative of a valvular lesion, is of the utmost importance in the diagnosis of myocardial disease.

In pure mitral stenosis the first sound is altered in a characteristic manner; it becomes short, sharp, and clear, like a sudden snap. It may resemble the second sound so closely as to be mistaken for it, especially when the second sound is not well heard at the apex. In fusiform dilatation of the aorta beyond the ring, the second sound is sometimes not only accentuated but resembles the sound produced when a cork is drawn from an empty bottle. The second sound in the aortic area may be diminished and even practically absent in true aortic stenosis, the fusion of the cusps being such as not to allow such apposition as is necessary to cause an aortic second sound of the usual loudness. These auscultatory phenomena are of considerable diagnostic value.

INTERPRETATION AND SIGNIFICANCE OF MURMURS.

During recent years much has been written and a good deal of controversy has arisen regarding the significance of murmurs. I am not going to enter this field of controversy, but may I be allowed to remark that it seems to me that a good deal of misunderstanding has arisen because the same terms are employed in different senses by various writers. Thus, some use the term physiological, as applied to murmurs, as synonymous with the term functional employed by others. They are not synonymous, for, while functional murmurs may include what are called physiological by some writers, a murmur may be functional but not physiological, as, for example, relative incompetence of the mitral valve from dilatation of the left ventricle.

In the case of functional or inorganic murmurs, the valves themselves are healthy, in contrast with organic murmurs, in which the valves are involved. Functional murmurs are of frequent occurrence, and in every case in which a murmur over the precordium is audible, the question whether the murmur is functional or organic should be most carefully considered.

Functional murmurs include, among others, 1, bruits due to anemia; 2, those due to relative incompetence of one of the valves; 3, cardiopulmonary murmurs, and 4, murmurs which may be present when there is excitation of the cardiac action, as, for example, in Graves's disease.

Relative incompetence may be due to, 1, dilatation of the cavity of the ventricle; 2, enlargement of the orifice on account of relaxation of the surrounding

---

*Read at a meeting of the Life Assurance Medical Officers' Association, London, January 4, 1921. The substance of this paper was published in a recent issue of the *Lancet*.

muscular structures; 3, enlargement of the ventricular cavity and dilatation of the orifice combined; and 4, owing to the shrinkage or stretching of the musculi papillares or chordæ tendineæ, as a result of disease. The condition is more common on the right than on the left side of the heart, and is almost unknown in aortic disease, being not nearly so frequent as in the case of the mitral valve. With regard to relative tricuspid incompetence, it should be remembered that the reflex of a certain amount of blood through the tricuspid orifice may occur under physiological conditions. In severe muscular exertion, for example, where the intracardiac pressure on the right side of the heart is excessive, a natural function of the tricuspid valve is to provide for a certain amount of regurgitation, and thus afford relief to the temporary embarrassment due to distention of the right ventricle.

Pathological relative incompetence is always consequent to some other condition. It may result from chronic Bright's disease or aortic disease, resulting in dilatation of the left ventricle and venous stasis in the lungs, mitral disease, and affections of the lungs which cause embarrassment in the pulmonary circulation, such as emphysema, cirrhosis, chronic fibroid tuberculosis, and chronic diseases of the bronchi. Among other causes are pulmonary stenosis or regurgitation, wasting states, toxic influences, such as alcoholism, lead, pneumonia, and diphtheria, acute febrile conditions, anemia, acute myocarditis, and myocardial degeneration. Relative incompetence is a somewhat common cause of mitral regurgitation. It may be due to simple overstrain of the heart, wasting states, toxic conditions, such as alcoholism, lead, pneumonia, and diphtheria, acute febrile affections, anemias, Graves's disease, acute myocarditis, fatty or fibroid degeneration of the myocardium, supernormal blood pressure, chronic Bright's disease, or aortic incompetence. Cardiopulmonary murmurs are murmurs produced outside the heart.

In investigating a murmur with regard to life insurance, the following points should be carefully noted: 1, The time of its occurrence; 2, the point of maximum intensity; 3, the direction of selective propagation—by which is meant that, instead of murmurs being audible equally well at all points of the chest wall from their points of maximum intensity, they are heard at a distance better in some directions than in others; and 4, its character. In every case the applicant should be examined in the standing posture and lying down, before and after gentle exercise, and during the various phases of respiration. May I point out that if a murmur is audible over more than one valvular area, it must not be inferred that more than one valve is necessarily affected. In order to be assured that this is the case, we must satisfy ourselves that there is either an increase in the intensity or an alteration in the character of the murmur, as the second area is approached; in other words, when more than one valve is affected, murmurs have separate points of maximum intensity.

Functional murmurs as a group present certain characteristics. They are almost invariably systolic in time, are often of short duration, and tend merely to accompany and not replace the cardiac sound. The point of maximum intensity is much more frequently in the pulmonary area, or rather below or external to it. While functional murmurs tend to be audible over the greater part, or even the whole of the precordium, their area of conduction outside the precordium is limited and their direction of selective propagation frequently does not coincide with that of organic murmurs. They are usually soft and blowing but are occasionally loud and rough in character. Their loudness not infrequently shows considerable variation from time to time. They are usually louder after exertion, and, indeed, may only be audible then. They vary with changes of posture, being usually louder when the individual lies down, and feebler or even absent in the sitting or standing posture.

Hemic murmurs are always systolic in time and are most frequently heard in the pulmonary area, next most commonly in the mitral area, the tricuspid area, and the aortic area—in the order named, the last named being comparatively rare. Cardiopulmonary murmurs are not absolutely synchronous with the beginning of systole or diastole and may precede or follow either; the point of maximum intensity does not coincide with any of the valvular areas, the murmurs being usually heard best over the margins of the lungs; and they vary with the phases of respiration.

If I were asked what significance I attached, from the point of view of life insurance, to the presence of a systolic murmur audible over the precordium, my reply would be that it entirely depends upon whether the murmur is organic or functional, and, if the latter, in which group the murmur should be placed. For example, cardiopulmonary murmurs may be totally disregarded as far as the heart itself is concerned.

SOME POINTS IN THE DIAGNOSIS OF THE VARIOUS FORMS OF CHRONIC VALVULAR DISEASE.

In conclusion, I should like to deal with some points regarding the diagnosis of the various forms of valvular disease. The fact is not sufficiently appreciated that it is not justifiable to make a diagnosis of aortic stenosis from the mere presence of a systolic murmur over the aortic area, additional evidence being required, as the murmur may be due to other causes. Among these causes are bruits due to anemia, murmurs associated with respiration, pulmonary stenosis, patent ductus arteriosus, pressure upon the aorta by a mediastinal tumor where no definite pulsation is present, mere roughening or stiffness of the aortic cusps or orifice, fusiform dilatation of the aorta just above the valve, what is called relative stenosis, and aneurysmal dilatation of the ascending aorta.

A diagnosis of aortic stenosis can readily be made when the following may be noted: The characteristic pulse, already described; displacement chiefly downwards and slightly outwards of the apex beat; a gradual, slow rise of the apex thrust—a slow heave, which is sustained; an aortic systolic thrill and murmur, with the direction of selective propagation upwards along the vessels of the neck, and a diminished or absent second sound. These features combined distinguish the condition from others that may give rise to a systolic bruit with its point of maximum intensity over the aortic area; when, however, only one or a few of these characteristic features are present, difficulty with regard to diagnosis may easily arise. Murmurs due to anemia and those associated with respiration have already been described.

One point alone is sufficient to distinguish aortic stenosis from pulmonary stenosis; in the latter, the murmur is never propagated into the arteries at the root of the neck. Further, the respective pulses differ materially in character, while in aortic stenosis there is evidence of hypertrophy of the left, and not of the right, ventricle, and the apex beat is characteristic. The physical signs of patent ductus arteriosus are a thrill and a murmur, having their point of maximum intensity in the second left intercostal space at least two inches from the middle line. The murmur is prolonged and occupies both systole and diastole; it commences shortly after the beginning of the first sound, and extends into a considerable part of the diastole; indeed, it may even persist almost throughout the whole cardiac cycle. It is not propagated to the vessels of the neck. This characteristic thrill and murmur may also be met with in arteriovenous aneurysm.

In the case of pressure upon the aorta by a mediastinal tumor where no definite pulsation is to be felt, the murmur is often audible over the vessels of the neck. An area of impairment may usually be detected, however, and there is rarely any alteration in the character of the second sound. When an aortic systolic bruit is due merely to roughness or stiffness of the aortic cusps or orifice, there is an absence of the characteristic pulse, of hypertrophy of the left ventricle in a young person who is free from kidney disease, and of the characteristic apex beat. In fusiform dilatation of the aorta just above the valve, the murmur is often heard over the vessels of the neck, but occasionally the area of impairment at the level of the second and third costal cartilages extends further out to the right than the normal limit, and the second sound is not only accentuated but is low pitched, ringing, and usually audible over a much wider area. As a rule, there is very little difficulty in diagnosing aortic stenosis from aneurysmal dilatation of the ascending aorta.

There is little or no difficulty in recognizing aortic incompetence in the great majority of cases. The characteristic radial pulse, the high pulse pressure, the greatly exaggerated pulsation of the arteries, the physical signs of hypertrophy of the left ventricle, the characteristic murmur, capillary pulsation, and, rarely, visible pulsation in the superficial veins, present a definite clinical picture with regard to the diagnosis of which there should be no mistake. It should be remembered, however, that the capillary pulse and pulsation of the superficial veins are occasionally also seen in other conditions. The murmurs of Duroziez is pathognomonic of the lesion. May I remind you that while typically the point of maximum intensity of an aortic diastolic bruit is over the inner end of the second right intercostal cartilage, it is frequently in the second left space, or immediately over the sternum, or, more rarely, at a lower level than this, approaching even the level of the apex beat, and in my experience more often nearer the left than the right border of the sternum. When the point of maximum intensity of the murmur is in the pulmonary area, the condition may be mistaken for pulmonary incompetence.

In this event, the points which should be remembered in considering the differential diagnosis are that pulmonary incompetence occurs more frequently in early life, that the pulse is not collapsing in character, that there is an absence of greatly exaggerated pulsation of the arteries and of capillary pulsation, that there is evidence of hypertrophy of the right, but not of the left ventricle, and that the accompanying murmur is very rarely propagated far down as the apex of the heart, and is never audible over the carotid artery. Dyspnea, cyanosis, and clubbing of the fingers are also more suggestive of pulmonary incompetence. It should be remembered, however, that both lesions may occur in the same individual, in which case there is usually a blending of the physical signs of both conditions. I have occasionally seen a diagnosis of mitral stenosis made in cases of aortic incompetence, when the point of maximum intensity of the diastolic bruit—especially when the bruit is only audible toward the latter part of the long pause—is as low as, or lower than half way down the sternum and on the left side of the middle line, and especially so when it is near the apex beat. The points of differential diagnosis are the following: In mitral stenosis the pulse is markedly different from that of aortic incompetence, and, further, there is an absence of greatly exaggerated pulsation of the arteries and of capillary pulsation, there is evidence of hypertrophy of the right but not of the left ventricle, the murmur is harsher in character, the first sound is short, sharp and clear, and the area of the thrill and murmur is usually very limited.

As far as my experience is concerned, more mistakes are made with regard to the diagnosis of mitral stenosis than any other valvular lesion. The lesion is often unrecognized, as the locality of the characteristic apical presystolic murmur is not infrequently limited, and the area may not be larger than one inch in diameter, while on the other hand a mere reduplication of the first sound is sometimes mistaken for mitral stenosis. The diagnosis is easy when the following conditions are present: The characteristic pulse; an apical presystolic purring or an apical diastolic thrill; evidence of hypertrophy of the right ventricle; an apical presystolic murmur or an apical diastolic murmur; a short, sharp, and clear first sound; and a reduplicated second sound. The thrill is almost pathognomonic. Some writers believe that a similar thrill may be present in aortic incompetence, and, therefore, that this affection should always be first excluded. The thrill must be distinguished from a mere vibration of the chest wall, which may be occasioned by a forcibly acting heart when the ribs are rigid, in the manner already described. The murmur is sometimes not detected, on account of the area over which it is audible being very limited; or in some cases there is from time to time a complete absence of thrill and murmur. In the latter case, we are justified in inferring that in all probability mitral stenosis is present from the character of the pulse and first sound, together with evidence of hypertrophy of the right ventricle and accentuation or reduplication of the second sound.

Some writers are of the opinion that a rumbling presystolic bruit is sometimes heard in the case of adherent pericardium in children. Even if this is so, the bruit is not rough and vibratory in character, neither does it terminate abruptly at the first sound, nor is the first sound modified in the way already described, and further, there are usually definite physical signs of adherent pericardium. As it is generally believed that a presystolic murmur at the apex is heard in certain cases of aortic incompetence, the question whether mitral stenosis is present in addition to aortic incompetence has occasionally to be considered. In this connection it may be noted that Flint's murmur has not the harsh and vibratory character which is commonly found in a presystolic bruit due to mitral stenosis, and if a thrill is present it is not purring in character. It should be borne in mind that both lesions may be present at the same time, and it is sometimes difficult, therefore, to say whether the murmur is that described by Flint or one due to the presence of mitral stenosis. In coming to a decision, the character of the murmur, the thrill, and the pulse—the characteristic collapsing pulse of aortic incompetence being modified if mitral stenosis is present as well—will be of assistance.

Mitral stenosis is sometimes unrecognized in cases in which there is associated incompetence; the presystolic murmur, instead of ending in the first sound, ends in a systolic murmur, and a diagnosis of a long systolic murmur is erroneously made. There is, however, a difference in character between the former and the latter parts of this continuous bruit, the earlier portion being rough and vibratory in character, and the latter blowing or musical. Further, we can observe the position in the cardiac cycle of the two parts of this continuous murmur by placing the fingers upon the apex beat or over the carotid artery.

When the second sound at the apex has disappeared, the presystolic murmur may be mistaken for a systolic murmur, and the modified first sound for the second sound. In this event, a differential diagnosis can be made from the difference in character of the two murmurs, from the fact that a presystolic murmur ends, while a systolic murmur begins with an accent, and by timing the murmur in the manner already indicated. When, in addition to the absence of the second sound at the apex, there is also no bruit present, mitral stenosis may not be recognized and a diagnosis of dilatation of the left ventricle made; in dilatation, however, a second sound is audible.

With regard to the diagnosis of mitral regurgitation, it is necessary to point out that a systolic bruit audible over the apex of the heart is not infrequently erroneously interpreted as indicative of organic disease of the mitral valve, when in reality the murmur is functional. In order to say that a mitral systolic murmur is indicative of organic mitral incompetence, we must satisfy ourselves that certain other physical signs are present. With this object in view, it is advisable to note, 1, the position and character of the apex beat; 2, the area and propagation of the murmur; and 3, the existence or absence of accentuation of the pulmonary second sound. In the case of a mitral systolic murmur due to organic valvular disease, owing to the presence of hypertrophy of the left ventricle, the apex beat is usually displaced downward as well as outward. When the degree of valvular disease is so slight that no definite downward displacement of the apex beat is present, its force is almost invariably increased, whereas in functional conditions it is likely to be less forcible than normal. If the murmur is propagated toward the angle of the scapula beyond the midaxillary line, we may be practically certain that it denotes the existence of organic disease. A definite accentuation of the pulmonary second sound, provided there is no condition of the lungs to account for it, is in favor of the view that we are dealing with organic disease. The diagnosis is further strengthened by evidence of the existence of mitral stenosis. The diagnosis of relative mitral incompetence due to chronic Bright's disease or to aortic disease from organic mitral incompetence is particularly difficult, since chronic nephritis and aortic disease in themselves give rise to hypertrophy of the left ventricle. In these cases the history of the case is of importance.

In addition to the points of differential diagnosis just enumerated, murmurs due to anemia and those associated with respiration have other distinguishing features. These have been referred to. Pulmonary stenosis is usually congenital and it is not my intention to deal with the diagnosis of congenital heart disease. All I would do is to point out that a diagnosis of pulmonary stenosis should not be made from the mere presence of a systolic murmur having its point of maximum intensity in the pulmonary area, as the murmur may be due to other causes.

The diagnosis of pulmonary incompetence is frequently a matter of considerable difficulty. The lesion with which it is most likely to be confounded is aortic incompetence, because the point of maximum intensity of the thrill and murmur of the latter is not infrequently to the left of the sternum. The differential diagnosis between these two conditions has been discussed under aortic incompetence.

In by no means an inconsiderable proportion of cases of tricuspid stenosis the lesion is entirely overlooked, no doubt on account of the absence of any murmur. It the opinion of Mackenzie, we may infer that tricuspid stenosis in all probability exists when pulsation of the liver is found to be auricular in type. The differential diagnosis of tricuspid and mitral stenosis is often a matter of great difficulty. The early appearance of marked cyanosis and of extensive dropsy are features in favor of the existence of the former lesion. When the point of maximum intensity of the murmur is strictly in the tricuspid area we can be fairly certain of the diagnosis. A diagnosis of tricuspid incompetence may undoubtedly be made when, after being emptied from below by means of the finger, the jugular vein rapidly fills from below, and when pulsation of the liver occurring synchronously with the apex beat, evidence of enlargement of the right side of the heart, a soft blowing systolic murmur having its point of maximum intensity in the tricuspid area, and diminution of the pulmonary second sound are present.

Miraculous Herbs

A Psychological Problem in Ethnology

By JONATHAN WRIGHT, M.D.,
Pleasantville, N. Y.

There is at present more of a tendency among ethnologists to take issue with Mr. Tylor than a few decades back, so far as the doctrine is concerned with which his name is especially associated. It can subtract nothing from the great guerdon of praise due him for having pointed out how similar are the workings of the mind of man in a similar environment to demur a little at some of his less important conclusions, but one of the things that will stand out in what I have to say here is the similarity of the phenomenon apparently associated in its most marked and typical manifestations with eras, or, in a broad way, with an era in the evolution of common belief among people, most of them thought of by us as oriental. The intense almost unreasoning belief in the efficacy of a certain drug or herb has become somewhat foreign to the modern mind, at least in the west, but we must at once admit that all gradations of this reverence are still seen on every side of us. The application of it is diffuse, though in general it is less universal, but it keeps alive innumerable nostra and fills the coffers of newspapers, scarcely less numerous, with funds derived from their advertising columns. Nay, this very primitive credulity is a great asset in the regular, I mean the legitimate and ethical practice of the art of medicine. All this is too familiar even to the layman to need anything more than an allusion. When, however, we meet with it as a manifestation of national even racial culture, when we observe practically all the individuals of a race at some more or less extended epoch believing unquestionably in the efficiency as a cure-all of some herb which modern science knows has little or no physiological action on the human system, we are at once face to face with a phenomenon which ought to be of as intense interest to psychology in its broad sense as it is to ethnology in a more specialized way.

These are the two leading topics of interest which are intimately associated with what I shall have to say, in a purely objective way, as to the ginseng, silphium, soma, haoma, and less at length as to other herbs now better known and of more powerful therapeutic action, as they are held in popular estimation. The universality of certain ethnological traits is a well worn subject and individual credulity is a familiar phenomenon to us all, but racial credulity when focussed on one subject, has been less often brought to the attention even of men of science. It is a legitimate part of the psychology which is being every day more and more studied in its application to small groups or to those of larger size and complexity. In the future it is bound to be much more developed, for it is not only of exceeding interest but it is manifestly of the greatest importance to know why men, in such large groups, think thus and so. For various reasons, chiefly because we ourselves are immersed in the modern crowd, it is more promising of practical results than is ordinarily postulated of the study of antiquity and antique man, to dwell a little on the foolish preoccupations of past ages rather than on those of our own day.

"Where the world wide doctrine of disease demons has held sway, men's minds have scarce had room for thought of drugs and regimen" (1). Now this is one of the minor points in Tylor's discourse to which even the parlor ethnologist may from the records of the observers far afield take exception. From these it is not superfluous for the purpose of this exposition to quote a small part of the evidence that the herb or other article nearly always has its part in the play between demon and disease, either as adjuvant or antidote to the demon's activities. This of course does not, as Ratzel remarks (2), absolutely exclude all reasonable study of phenomena. Even when he made a real discovery he had to surround it "with the hocus pocus of fetish rites and ceremonies" (3), The higher ranks of the profession always include one "who performs on a mat" (4). In the sanctuary of a Malay medicine hut the walls and roof hang with tufts of dry plants, but scattered over the floor lie bamboos covered with incised patterns of Malay magic (5). It is hardly correct then to say that the primitive medicine man has no room in his mind for drugs and regimen. He has them in mind but he uses them on a false therapeutic theory. The results, the phenomena are the same as in our culture, but he explains them differently. He selects his plant with reference to his conception of some demon who is preying on the insides of his patient, and when it is the castor oil plant he often rejoices in the evidence of a successful diagnosis. The bacteriologist is happy in the same confirmation of his theory.

I have often before insisted on the similarity in the facts or proof on which men rest their beliefs, but here I repeat it, to insist that whether the medicine man practises with a materia medica arranged on magical or bacteriological lines the drug or the herb is there for his use, and if it was once reverenced more than it is now or in China more than it is in New York, it is because the system on which its administration is based is worthy in the eyes of ancient or Chinese mankind of more reverence than other explanations vouchsafed at other points of time and space. Now this is a state of mind. It is just as much an objective phenomenon as the castor oil plant. I do not urge that bacteriologists have solved all the questions of etiology, but the culture out of which bacteriology sprang is here confronted by a psychological problem which demands from history and ethnology an explanation which is not forthcoming. Why did the bushman or the Chinaman think thus? Ignorance? We, in detached moments, acknowledge we are ignorant enough. We congratulate ourselves, when in another, a vaunting mood, that we have pulled ourselves bodily out of many of the devious mental channels, along which the primitive man paddled his canoe, but we still float on the broad bosom of the sea of uncritical credulity.

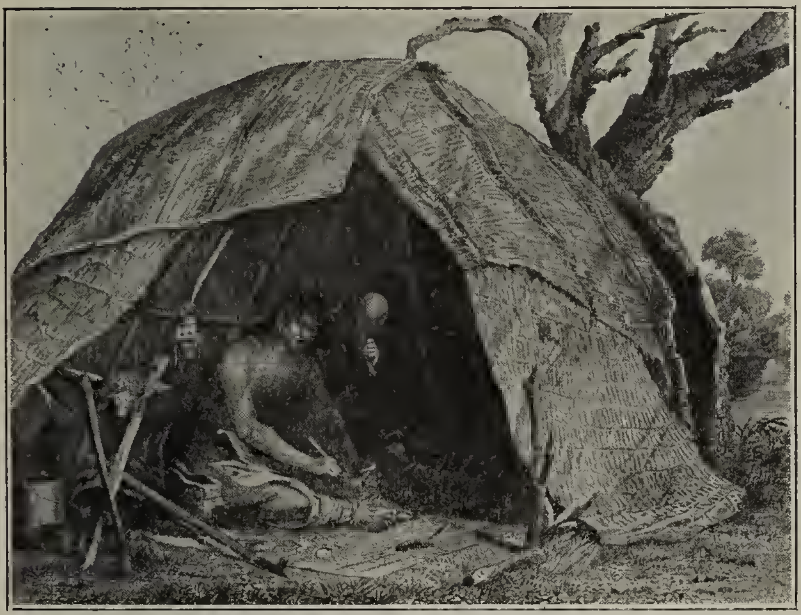

FIG. 1. (Schoolcraft.) Medicine man's hut.

This is a long introduction to the statement of a problem which is the chief object of this paper, but if it in any way helps toward an efficient solution, psychological as well as historical and ethnological, it may be pardoned. It would still be incomplete, however, if I have not made it apparent that I lay aside the phenomenon of the individual medicine man's state of mind, whether primitive or modern, whether Chinese or Yankee. I am referring to the state of mind of a race or an epoch or a jungle, not of an individual, however omniscient. With all the temerity of a dilettante, which is sometimes attractive from its mere freshness, I have ventured to modify a little the unguarded generalization of Tylor and perhaps it is equally superfluous to point out that the addiction of exceptional intensity manifested by remote cultures to some drug or plant, while apparently arising independently and based on the same folk psychology, is not always manifest to us in a study of primitive man and ancient culture in exactly the same terms. We know ginseng and silphium and peyotl and many others are actualities, but we are not sure that the *soma* of the Persians and the *haoma* of the Hindus were ever anything but a sort of mystical conception of their priesthood, possibly only a part of their ritual. If that is so, and it is only a suggestion, perhaps borrowed by me from another, it still does not alter the fact that there existed in a narrow circle of priestly craft a conception of a panacea, dimly traceable in the legend of Æsculapius and his daughters. Ginseng, silphium and other drugs innumerable have been panaceas more widely disseminated and not so exclusively confined to the family circle of the Asclepiadæ. Panaceia and Hygeia were the daughters of Æsculapius. They were doubtful figures in the old Greek myths and were much confused in practice. It was long before they stood for differentiated activities, but in later times they underwent a factitious differentiation. Since the decline of our faith in drugs we have almost again arrived at the viewpoint from which we shall be ready to declare that Hygeia, fully evolved, is as near Panaceia as any identical twin can be—that hygiene is in a fair way to become the true panacea. We must all die, but as Pat said, there is always a cure for every disease but the last one. We even hope by the intervention of Hygeia to arrest senility and delay death itself.

Though our interest lies entirely with the widest circles it cannot lose sight of the fact that racial credulity in its attitude toward therapy is to a large extent closely related to individual credulity, but crowd psychology in its manifestation of mental contagion becomes, or should be, vastly more impressive and furnish to the individual practitioner of medicine a weightier lesson than his individual experience. He knows how firmly fixed is the faith of his patients in the curative power of drugs or regimen possessing no therapeutic value except what the patient's credulity gives them. It is scarcely otherwise with primitive man. Many years ago Powell (6), taking the *Dispensatory* (U. S.) as a standard, thought about twenty-five per cent. of the whole number of herbs used by the Cherokees were properly employed, that is, used largely because of a definite physiological action according to that standard. In the forty years which have elapsed since the publication of that standard, accepted in Powell's day, one may suppose there has been a considerable shift of opinion as to the physiological and more as to the therapeutic value of the herbs involved, but it is not possible here to discuss that. It is quite evident that the vast majority of all herbs of antiquity, used in doctoring, are today valueless in the opinion of the practitioner. In that majority are to be included, with slight excuse for taking exception to the statement, the herbs with which I hope to illustrate what I have advanced—that there is a psychological problem involved for the ethnologist as well as for the practitioner of modern medicine.

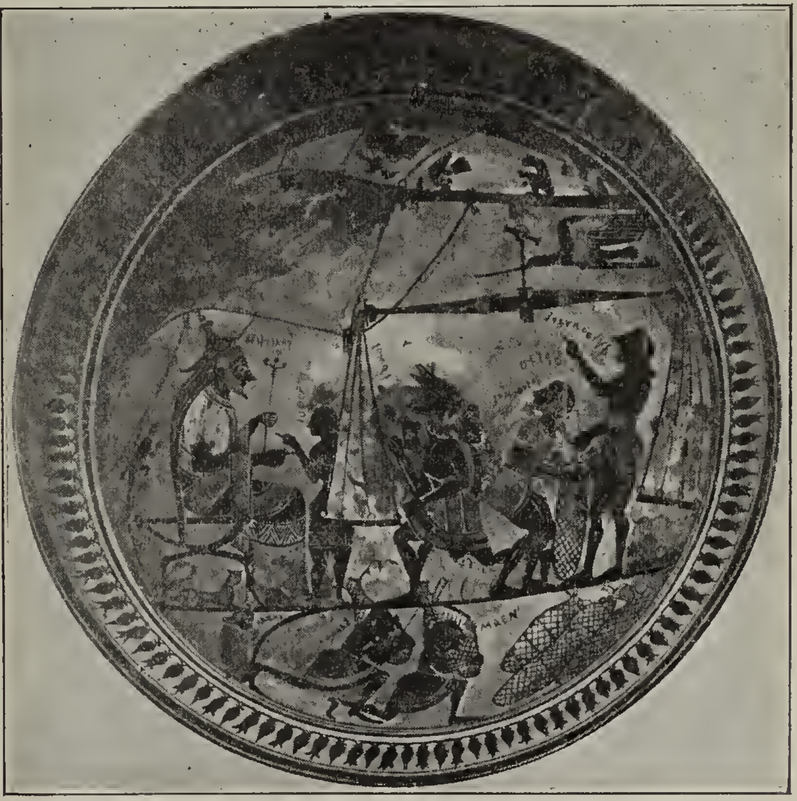

FIG. 2. (Babelon). Archelaus and the silphium.

Having thus disposed of definitions and explanations and circumnavigated as well as I can the shoals of exceptions and objections to the claim that the problem is one at all apart in any of its manifestations from others concerned with the psychology of man, I trust I can at least be brief in summarizing the outstanding objective factors in the problem as they are to be found in history and the less specialized paths of ethnology, and I shall here attempt no contribution to the solution of the question as to the foundations of the beliefs of men.

In the Persian *Zend Avesta* (7), it is true, the highest order of healer was he who performed his functions by means of holy words and we may place him along side of the primitive doctor, "who performs on a mat," but here again closely allied to these incantations, this hocus pocus the missionary calls it, were the herbs. From the plants which spring up by thousands around the body of the primordial bull Gaokerena, fifty kinds growing from the body itself, Ahura Mazda brought forth the healing ones. The only thing here definitely advised was the *haoma.* Though the haoma plant, at least etymologically, is the same as the Hindu *soma,* and is one of the many links which connect the two cultures as essentially those of one race in remote antiquity, it has never been identified. On earth it perhaps eventually lost much of its reality through being transferred in the liturgy to heaven, but it bespeaks the existence once on earth of some plant especially calling for reverence because of the supposed virtue it contained in the estimation of a race, a race which was a conquering one and founded one of the oldest and mightiest of civilizations, whether Aryan or not or what the exact route of their migration. In the *Zend Avesta* we read:

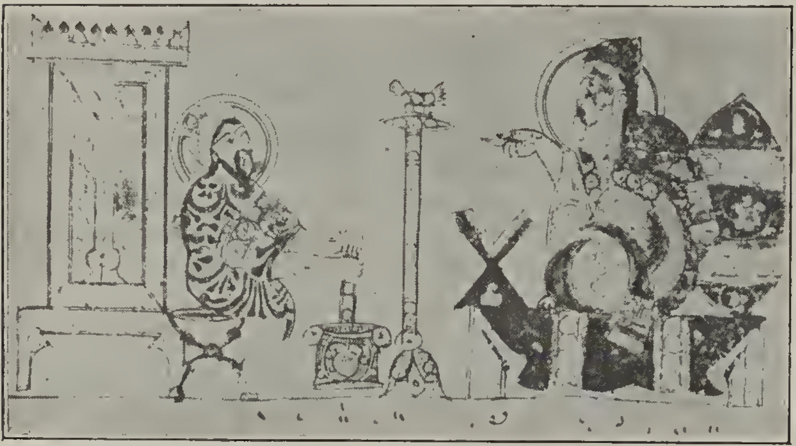

FIG. 3. From an early medieval manuscript of Dioscorides, with Arabian descriptions.

> "There are two Haomas: one is the yellow or Golden Haoma, which is the earthly Haoma and which, when prepared for the sacrifice, is the king of healing plants; the other is the white Haoma or Gaokarena which grows up in the middle of the sea, Voura-kasha, surrounded by the ten thousand healing plants. It is by the drinking of Gaokarena that men, on the day of the resurrection will become immortal." (LXIX)

In the Hindu epic, in the *Rig Veda* (8), the reference to the *soma* plant is no less impressive and it appears in many of the hymns,

> "I took some *soma* when the sun rose up, O Mitra Varuna. That is the sick man's medicine." (Book VIII, Hymn LXI).
>
> 6. "He who hath store of herbs at hand, like kings amid a crowd of men—
> Physician is that sage's name, fiend, slayer, chaser of disease,
> 7. Herbs rich in *soma,* rich in steeds, in nourishment, in strengthening power,
> All these have I provided here, that this man may be whole again."
>
> 21. "All plants that hear this speech, and those that have departed far away
> Come all assembled and confer your healing power upon this herb.
> 22. With soma as their sovereign lord the plants hold colloquy and say:
> 23. Most excellent of all art thou, O plant; thy vassals are the trees." (Book X, Hymn XCVII).

Here the critics (9) are a little more positive in conjecturing that the soma is some kind of a milk weed whose fermented juice causes intoxication. If we are to identify it as hashish, on the strength of the reference in Herodotus (10) to the Scythians and the island dwellers of the Araxes, we would rank this reverence of Persian and Hindu with what we know from Safford (11) of the peyotl of our southwest which he thinks the Aztecs also had. This would be a class whose psychological relationship places it in one with opium and alcohol.

If we have to depend on deification for evidence of the profound belief a whole people once had in the soma or the haoma, we are driven more forcibly to the same conclusion as to the silphium plant for the people dwelling in the basin of the Mediterranean in the time and prior to the time of Hippocrates, but from quite a different kind of evidence, chiefly that of price. Soon after the Hippocratic era its vogue began to lessen despite the fact it became much more rare, though it was a precious article even in the time of Cæsar. We miss it in Homer and Hesiod, though in the former we get mention of the wonderful moly which was administered by Circe in the Odyssey (12). We first meet the silphium in Herodotus, who says he lived four hundred years after Homer. It was found, he says (13), on the Mediterranean coast of Africa in Cyrene, roughly corresponding in its extension to the coast from Tunis to Tripoli, a territory of wonderful fertility for Africa, from the island of Platea to the mouth of the Syrtis. He says, "weasels are produced in the silphium, very like those at Tartessus," and Aristotle (14) remarks: "In the plant silphium is found a small serpent." What these passages mean I cannot imagine, but evidently something with affinity to African magic. I will not stop to specify the references to its physiological properties as Hippocrates believed in them. In the index to Littré's edition (15) they are readily found. It was a moderate stomachic and intestinal irritant, ranking apparently below the hellebore and the euphoribæ as a purge and possessing some carminitive properties, but its

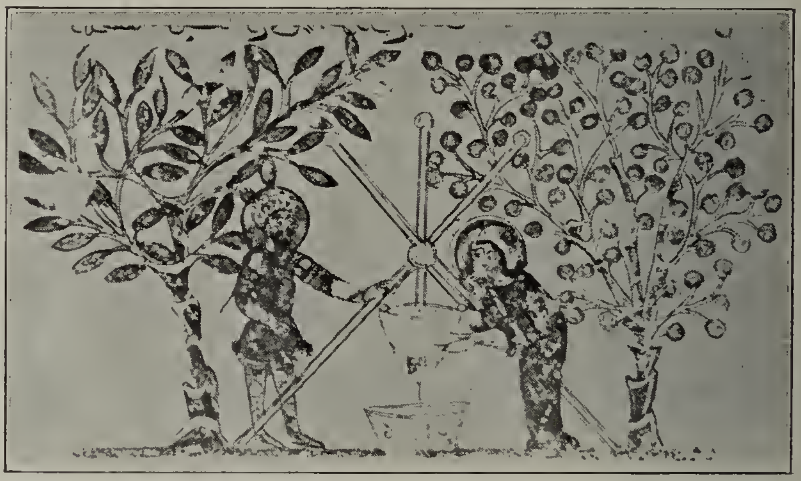

FIG. 4. From an early medieval manuscript of Dioscorides, with Arabian descriptions.

use, even in *Hippocrates,* places it among the panaceas, external as well as internal. Stalk, leaf, root, juice, all possessed more or less of the virtues so highly prized that in Aristophanes's plays (16) we find it used as a synonym for wealth.

It was the source of the wealth of the Battidæ, rulers of Cyrene. Sophocles in a tiny fragment (603, Pearson) evidently is referring to their territory when he speaks of a "meadow of silphium." He who had the most of silphium stalks in his strong box was indeed a rich man. Not as a medicament only, but as a condiment, it is spoken of both by Hippocrates and by Aristophanes. In the latter it is to be "grated over the meat, the dead bodies of the birds, with the cheese." Pliny (17), though he relates its virtues and magnifies the therapeutic value of it, said it had disappeared in his day from the African coast and was found only as an inferior variety in Syria and in a few other places. It could not be made to grow in Attica, but if the infatuation for it had not declined we may be sure that it would never have ceased to grow, carefully protected by the shepherds and the masters alike in Africa instead of being grazed down, as Pliny says, by the animals of the landlords of the sheep walks. A hundred years later, in Galen's time it had sunk to the average level of medicinal herbs of commerce, but when Cæsar plundered the treasury of Rome, besides the gold and silver, he found 1,500 pounds in weight of silphium. In the later Greco-Roman medical writers, it is mentioned indeed by Paulus Aegineta (18) and in his translation Adams makes a lengthy commentary on it referring to the chapter devoted to it by Dioscorides in the first and second century A. D., possibly after Pliny, but Cassius Felix (19) in the fourth or fifth, scarcely alludes to it. Under the Arabians it had its renaissance, but a comparatively feeble one. Although Theophrastus (20), the successor of Aristotle, described it with considerable care and much ingenuity, modern critics have, on the whole, failed to identify it. Ridgeway is said to have suggested it might be the lotus plant, certainly a very remarkable guess. Littré translated it asafetida in his earlier volumes but later abandoned that designation, possibly because de Candolle was quite sure it must be a species of Thapsia. No one has suggested any herb known to the modern pharmacopœia, which has ever been mentioned as likely to have been the silphium, worth the price paid for it in Athens in the time of Aristophanes. The only rival to it which has persisted in its reputation to modern times is the ginseng.

While it is sometimes said that the ginseng root, owing to its form, has a reputation among the Chinese as an aphrodisiac, that is properly only one of the magic properties ascribed to it. The materia medica of the west recognizes no therapeutic value of consequence in it, but there are many still alive who remember how once every hillside, in certain sections of the south and western parts of the United States, was searched for it. It was brought by woods-possibly after Pliny, but Cassius Felix (19) in the made large fortunes in exporting it across the Pacific, fifty years ago. How much of this traffic still exists I do not know, but in my boyhood it furnished a livelihood to many a trapper and hunter more sure by far than his skins, though what the magnitude of it was in figures I have never seen. On this side of the globe hundreds, doubtless thousands of men, sought an inert root for the treatment of millions of fellow beings in China ten thousand miles away. These facts are familiar practically to all of us. In order to present the Chinese evidence I make use of a foreign author, a traveler in China and Thibet, a Catholic missionary and a keen observer, well known two generations ago. I use a much later translation of Huc's *Travels in Tertary, Thibet and China* (21).

"Jin-seng is perhaps the most considerable article of Mantchourian commerce. Throughout China there is no chemist's shop unprovided with more or less of it. The root of jin-seng is straight, spindle-shaped, and very knotty; seldom so large as one's little finger, and in length from two to three inches. When it has undergone its fitting preparation, its color is a transparent white, with sometimes a slight red or yellow tinge. Its appearance, then, is that of a branch of stalactite. The Chinese report marvels of the jin-seng, and no doubt it is, for Chinese organization, a tonic of very great effect for old and weak persons; but its nature is too heating, the Chinese physicians admit, for the European temperament, already, in their opinion, too hot. The price is enormous, and doubtless its dearness contributes, with a people like the Chinese, to raise its celebrity so high. The rich and the mandarins probably use it only because it is above the reach of the other people and out of pure ostentation. The jin-seng, grown in Corea, is of very inferior quality to that of Mantchouria." The zeal with which it is still sought there may be gathered from the account of Colonel Younghusband (22): "At night we would put up in a sable hunter's hut. These are met with every twelve or fifteen miles, and each is the head-quarters of a party of hunters who trap sables and also seek the gin-seng root—the root of a plant upon which the Chinese set great store for medicinal purposes. But the gin-seng plant seekers would wander through the forest day after day and all day long, and if they found one plant in the season they would be content. This plant would be worth perhaps £15, for the Chinese believe the genuine wild plant to have the most wonderful properties."

I think most readers will agree, if they have followed my citations thus far, that we have here a problem that justifies the title of this paper. It is not only a problem for the psychologist and the ethnologist but a certain amount of instruction may be gathered from its study by the modern therapeutist.

Editorial Articles

THE DRUG PROBLEM

The drug problem is serious in all parts of the world and perhaps especially grave in this country. The habit has been always more or less prevalent here because there is a mixed population, including a considerable number from Asia in whom drug taking is as common as smoking in America and, to some extent, because California is sufficiently near to Asia to make it comparatively easy for habit forming drugs to be smuggled in. However, there appears to be no doubt that since the war the drug traffic for illegitimate purposes has increased immensely in all civilized countries and that it has become a menace to the health and efficiency of the population of all countries.

It seems that America is now awake to the magnitude of the evil and that drastic steps will be taken to suppress the traffic in dangerous drugs. As a matter of fact, the government has been aware of the gravity of the situation in this respect for some time and have caused to be passed extremely stringent laws to prevent the illicit sales of habit forming drugs. Moreover, these laws have been well administered but in spite of this, drug taking has been found to be greatly on the increase. So much was this the case, that in 1918 a special committee was appointed by the Federal Government to investigate the question, the report of which was published in June, 1919.

It is noteworthy that this investigation took place before prohibition came into force and therefore attention may be drawn to the fact that drug addiction was esteemed a matter for national concern some time before prohibition became law. The point is worthy of careful notice because it is contended by some that the great increase in the drug habit is due mainly to prohibition.. This law may have aggravated the habit, although there is little to prove that this is so, but it was a standing evil before. Indeed it has been proved that the use of alcohol and drug taking have flourished simultaneously.

The report is very illuminating on the subject. It shows that of all the civilized countries, of course, excluding all the countries of the Far East, the United States was the largest opium consuming country for which statistics are available. According to this report the per capita consumption of opium was as follows: Italy, one grain; Germany, two grains; Portugal, two and a half grains; France, three grains; Holland, three and a half grains; United States, thirty-six grains; Great Britain was not included in this list but if common report may be relied on, it now takes a prominent place among the European countries as an illicit consumer of dangerous drugs.

Another reason for the drug habit which has been sedulously fostered and propagated by those who presumably wish to cover its true causes, is that most of those who were confirmed drug takers became addicts owing to the careless administration of narcotics by physicians. This charge has been completely refuted and the good name of the medical profession restored as far as this calumny is concerned. It was found that the great majority of the victims were initiated when young, were mentally unstable, and fell into vicious hands; in fact, were exploited for the sake of profit. It was also found that, as a rule, treatment was futile, the vast proportion relapsing soon after they were discharged as cured. The trade is too profitable to allow its victims to reform if possible. Laws, even if stringently enforced, appear to be absolutely useless to prevent or to restrain to any appreciable degree the drug traffic, and the only means for effecting this purpose is to restrict the output. The manufacture and sale of habit forming drugs are profitable and therefore difficult to prevent, and yet the only certain mode of killing the illicit use of dangerous drugs is to restrict the output to the requirements of the medical and dental professions.

A RETROSPECT OF RECENT MEDICAL SCIENCE

It is a truism to say that medical science has progressed, as the proofs of this advance are before our eyes. However, there are some people who need to have their memories quickened in this direction, so that it is in the order of things to draw attention to certain conspicuous features which especially demonstrate this advance.

In the first place, the most remarkable public health event in civilized countries of the past twenty years or so has been the drop in the infant mortality rate. In America and in Great Britain during that period the fall has been progressively rapid, and, moreover, bids fair to continue. The result is mainly owing to maternity and child welfare work, which, by the way, has taken firm hold in all parts of this country.

Another striking piece of evidence of the manner in which medical science has advanced is the fact that people are living longer than formerly, and, as a rule, are a great deal more active in their old age than was formerly the case. This addition to the span of life may be rightly set down to the credit of medical science. With regard to longevity a somewhat curious but suggestive point has been brought out in some statistics of the Metropolitan Life Insurance Company published in the early part of this year, to the effect that overweight is a distinct disadvantage among insured lives, that is, overweight after the age of thirty-five or thereabouts, when it begins to be dangerous even in relatively small amounts. On the other hand underweight, at any rate after the age of forty, is a favorable omen for long life. Those who weigh between ten and twenty per cent. below the average show the best conditions for longevity.

While this may seem like a digression from the matter in hand, it may be borne in mind that medical science is concerned in keeping within healthy limits body weight, and more so than ever before in the history of medicine now that the value of diet is beginning to be understood at its true worth and the functions of the endocrine glands and the vitamines are commencing to be correctly estimated. Of course, in the advance of medical science, the discoveries with relation to the endocrine glands are by no means the least important and suggest amazing possibilities in the way of treatment, some of which even now appear to be on the high road to fulfillment.

As for the triumphs which medical science have won over epidemic diseases, that is an old story which he who runs may read.

With regard to cancer, in this country, at least, there seem to be signs that some progress is being made in treatment and prevention. Probably, these are the fruits of the educational campaign, that people come for advice and treatment in the early stages of the disease when measures calculated to cure the disease can only be effective.

A certain amount of progress has been made in the treatment of tuberculosis, but it must never be forgotten that pulmonary tuberculosis is essentially a house disease and it is in the improvement of domestic hygiene and of environment generally that its successful treatment and prevention may be looked for. Public sanitation has done and is doing great things in the interests of health and it is now time that attention was particularly paid to housing and domestic hygiene. Not only are inadequate and unhygienic houses and city environment the root causes of tuberculosis and its development but of several other preventable diseases.

Apart from tuberculosis, cancer and influenza, there is altogether too much of what may be termed general sickness and a considerable part of this general sickness, among children in particular, is due to unhealthy home conditions which should be remedied at once, no matter how great the cost.

With respect to parasitic diseases medical research has done and is doing valuable work. Fortunately in this country medical research is not starved. The rich men of America have the vision and imagination to realize that any money expended in the furtherance of health will be returned one hundredfold. The presence of disease is a menace to the community. Those who are not in good health cannot work zestfully and energetically and are discontented and a large discontented element in the population is dangerous to the body politic. However, it is well known that it is to the advantage of all that the members of a nation should be healthy, and it follows that it is equally obvious that money expended for the attainment of this object is money well spent. No money could be better spent than for medical research.

THE ACUTE CARDIOHEPATIC SYNDROME IN CHILDHOOD

The acute cardiohepatic syndrome in children presents a variable onset and evolution. It may be sudden in development or, on the contrary, the onset may be slow. The former condition represents the acute, the latter the chronic type of the cardiohepatic syndrome.

The acute type of this syndrome arises in a large number of very different circumstances. All morbid processes which engender hypertension in the pulmonary artery system may provoke it. The infectious diseases likewise produce it, either by determining material lesions of the cardiac fibre or by simple junctional perturbations. These arise quite frequently in diphtheria, scarlatina and typhoid fever.

A detailed examination of the patient frequently reveals an increase of the cardiohepatic dullness. On the other hand there is tachycardia, the number of pulsations being in direct relation to the temperature. The tachycardia of course indicates a lowered blood pressure; the cardiac sounds are weak and distant, but quite distinct from the dull murmurs of endocarditis.

There exists an entire series of functional symptoms—more especially hepatic—difficult to identify in the morbid complexus. The syndrome may remain latent, while in other instances it may be the source of serious accidents, even of sudden rapid death. In reality, certain symptoms such as tachycardia, lowered blood pressure, weak pulse and dullness of the cardiac sounds may reveal glandular insufficiency, particularly hypoepinephria, but in these cases the heart remains normal in size. This distinction is not merely of dogmatic interest; it has very different therapeutical consequences because in cardiac insufficiency cardiac stimuli are indicated, while in glandular insufficiency opotheraphy is required.

The acute cardiohepatic syndrome is often encountered in acute articular rheumatism, usually associated with endocarditis and pericarditis. The intensity of the syndrome indicates the gravity of the cardiac involvement. The syndrome arises in the nephritides, especially those of scarlatina.

There is first of all a sudden marked increase in the blood pressure which is temporary, and this is followed by a drop in the pressure, after which the cardiohepatic phase begins.

The acute cardiohepatic syndrome of the nephritides is met with in adults as well as children, but with notable differences resulting from the quality of the tissues. In children the cardiac fibre is young, possessing all the proprieties of elasticity, toxicity and contractibility, and although these are momentarily lost, they rapidly return. Cardiac asthma, acute pulmonary edema, angina pectoris, and signs of left ventricular insufficiency met with in adults are absent in children, because in them the right ventricle readily becomes dilated. Sudden arterial hypertension causes paroxysms of eclamptic uremia in children just as it does in pregnancy. But in the circumstances under consideration, it is not an intoxication uremia, because the symptomatic phenomena are the result of arterial hypertension only; and if the heart and liver dilate the convulsive seizures do not occur, and if they have appeared, they cease as soon as the hypertension retrogresses and the cardiohepatic phenomena develop.

Hence it is clear that the cardiohepatic syndrome of the acute nephritides has a fair prognosis if appropriate treatment is resorted to in time. It is only exceptionally, and when the nephritis is prolonged, that the reaction on the heart and liver is likewise prolonged.

EDUCATION REGARDING CANCER

It seems to be generally admitted that cancer is on the increase in most civilized countries. Mr. Frederick Hoffman goes so far as to say that the mortality from this cause in this country is now approximately one hundred thousand a year, or equivalent to a rate of one hundred to the one hundred thousand of population. He also proceeds to say that the disease is increasing from year to year in practically every State, and in practically every community for which the records are available and trustworthy.

It is hoped that Mr. Hoffman is too pessimistic as regards the future, although there is no doubt that his object in making known the prevalence and increase of malignant disease in civilized countries, as it seems to be preeminently a disease of civilization, is most praiseworthy, namely, to draw public attention to the state of affairs and to frighten people, if necessary, into employing curative or preventive measures. It is further a matter of common knowledge that the only effective method known as yet for treating cancer is to deal with it in the early stages, the earlier the better.

Professor W. W. Keen, of Philadelphia, quoted by Professor A. Primrose, of Toronto, in an article contributed by him to the *Canadian Medical Association Journal,* March, 1923, has said, "If every woman who found a lump in her breast would consult a surgeon at once, that is to say, within forty-eight hours if possible, but in any case within a week, I am sure that eighty-five out of every hundred would be cured and stay cured." While other surgeons do not agree with Professor Keen in these conclusions, it is the opinion of one of the most distinguished surgeons of the world. In any event, it is a matter of universal agreement among members of the medical profession, that the treatment of cancer in the earliest stage possible gives the best hope of a successful or even of a satisfactory issue. In order to bring this about the educational campaign in this country was inaugurated and has been extended to embrace Canada and Great Britain. According to Canadian reports a good deal of enthusiasm has been aroused by the campaign just begun and it promises to be successful in that country. It is stated that as a result no doubt of this public education cancer cases are brought for treatment at an earlier stage than formerly and presumably the treatment, too, is more successful. The campaign in Great Britain will probably not make headway so rapidly as in this country and in Canada. The profession there is more conservative by far than on this side of the Atlantic and already several objections have been urged against the prosecution of a widespread public campaign.

It is not that in Great Britain the profession does not wish the public to be educated with respect to the early symptoms of cancer, but rather that by some at least the wisdom of certain of the methods adopted to carry out this education is doubted. However, there seems to be a general agreement that the propaganda in this country has had a good educative effect. As Dr. Billings has pointed out, with the cooperation of an enlightened, that is, of an educated public, the death rate from tuberculosis has been lowered, while typhoid fever, typhus fever and many other deadly epidemics have been almost eradicated under civilized peace conditions by the application of known and tried reliable means of prevention. It certainly is true that until the public becomes interested in the prevention of a disease little can be done, and therefore if it is hoped to prevent or even check the prevalence of cancer the public must be educated as to the methods of accomplishing this in order to be interested. And this education must come from the medical profession with the powerful aid of the lay press.

In concluding these remarks on educating the public regarding the early symptoms of cancer it may not be amiss to point out that there are general practitioners who are not skilled in the early diagnosis of malignant disease, who, in fact, but rarely meet with a case. Thus a certain proportion of the medical profession itself requires more practice in the diagnosis of cancer in its various forms and in its earliest stages, but, of course, this has been all provided for. Education regarding cancer widely disseminated should be a long step forward in the prevention of the disease.

MENTAL HYGIENE IN NEW YORK STATE

The Year's Work in Mental Hygiene is the title under which the New York State Charities Aid Association publishes in pamphlet form its annual report to the State Hospital Commission and that of its Mental Hygiene Committee. This pamphlet has recently been distributed to those interested.

The Mental Hygiene Committee has four main lines of work. It informs the public through lectures, exhibits, literature and published articles about the nature, extent, causes, treatment, and means of preventing mental diseases and defects. It promotes remedial legislation, and brings to the attention of the public and the proper officials the essential facts about the prevalence of mental disorders, and the financial and other needs of the State institutions for the care of the mentally diseased and defective. It promotes the establishment and effective operation of free clinics for mental disorders and defects, especially in connection with State institutions. Finally, it acts as a bureau of information about the examination and treatment of the mentally sick and deficient, and about institutions for mental disorders.

Among activities carried on throughout the year covered by the report were the holding of public meetings with addresses; the visiting and inspection of State hospitals for the insane and State schools for the feebleminded, with reports on the same to the proper authorities; the study of measures before the Legislature dealing with care and treatment, and the taking of appropriate action; bringing the needs of the State institutions to the appropriating authorities; cooperating in a health survey of Erie County conducted under the auspices of the National Child Health Council; maintaining a social service department which assisted 502 individuals toward better mental health and social adjustment; and furnishing to the Cornell Clinic until April 15th a psychiatric social service through which three hundred patients received advice, treatment and aftercare when necessary.

New legislation relating to mental diseases during the year created a centralized State Department of Purchase, and a cooperating Bureau of Standards; an amendment to the civil practice act provides a measure that has been long desired by State hospitals and other institutions, namely, that all writs of habeas corpus directed to the authorities of a State institution must be made returnable in the country in which the person is detained or before the nearest authorized official; a permanent commission on pensions, to inquire into the subjects of retirement, pension allowance, and annuities for State and municipal officers and employees, was created.

In November, 1921, a psychiatric clinic was opened under the auspices of the committee at the East Harlem Health Centre of the American Red Cross.

The report of the State Charities Aid Association to the State Hospitals Commission announces a special reappropriation of nearly $3,000,000 for the construction of a new civil State hospital at Creedmoor; and, in addition, the annual appropriation bill has allowed $1,989,500 for new construction and improvements at the thirteen State hospitals. From previous appropriations, 1,500 new beds will probably be made available before the end of the year. An overcrowding table shows an increase of almost two per cent. in overcrowding as compared with the previous year. This table shows the population, exclusive of paroles, of the State hospitals to be 37,713, their rated capacity, 30,484, which means an overcrowding of 7,299, or 23.7 per cent. Manhattan State Hospital on Ward's Island is tabulated with a population of 6,506, rated capacity, 5,047, overcrowding 1,459, or a percentage of 28.9. This statement is of exceptional interest as bearing on the tragic loss of life resulting from the recent fire there.

The association reports improvement of personnel in the hospitals, and of medical service. A great asset to the latter has been the purchase of x ray apparatus for several of the hospitals. Perhaps the most significant development of the year was the grant by the Legislature of a special appropriation of $13,700 for occupational therapy in the hospitals. An important new mental clinic was opened during the year at Troy by the Hudson River State Hospital. This makes a total of forty State hospital clinics now in operation.

The report closes with an urgent plea for larger appropriations to relieve the serious overcrowding, the greatest since the first year of the war. "The patients are now herded together with no chance for privacy or a feeling of space and freedom. . . . Beds everywhere, greedily absorbing every bit of available space—long uninterrupted rows of them in close formation; beds packed in so tightly in some instances that not even a finger's breadth separate them, so that the patient has to get in and out over the footboard; two beds as a regular thing in rooms designed for only one patient; many beds jammed into corridors; others so much encroaching upon day rooms that the patients have no suitable place in which to pass the long waking hours."

Another crying need for State care of the mentally sick is a system of State Psychopathic Hospitals. These should be established, not in New York City alone, but in every important population centre in the State., A beginning should be made at once in New York City .

POPULATION PROBLEMS IN NEW YORK

The 1920 Census Committee of New York City has recently issued a book entitled *Statistical Sources for Demographic Studies of New York,* which reveals some interesting figures and facts as to population.

New York City is now larger than the whole nation was in 1800. The increase of southeastern Europeans from 1910 to 1920 was nearly three fourths of a million, the total number of these citizens now exceeding the whole English stock of the country's first census. New York contains a tenth of the nation's stock of northwestern Europeans. During the increase of its southeastern white stock, there was a decrease of a quarter of a million of its northwestern European stock. Southeastern European born natives have increased from 47,595 in 1880, to 1,329,811 in 1920; northwestern Europeans have decreased from 630,885 to 599,140. It holds over a fifth of all the Italian, Hellenic, Slavic and Yiddish population of the nation. The Russian element, which is ninety per cent. Jewish, is more than a million in number, and its increase from 1910 to 1920 was greater than the increase of native whites of native parentage. This signifies that, in every one hundred persons of the whole population of the United States, one is of Russian birth or parentage and living in New York. Nearly one third of the city's population is of Italian and Russian parentage combined. More than a third of the foreign born living in the areas of high population density are of Russian derivation, and more than one fifth, Italian. The Italian element, also, showed an increase larger than the native parentage element.

Two thirds of this large and varied population is housed on less than ten per cent. of the area of greater New York. The rim of the city has grown two hundred per cent. in ten years; the hub, eight per cent.; and the suburbs even more. The districts in New York which have a population density of more than 219 persons per acre, the average density of London's most congested sections, still have 1,895,457 people; London had in 1911 less than 180,000 in districts where the population density is over 219 to the acre.

The death rate is lowest in the densest district of Manhattan, for reasons not yet fully known, one of them being the low susceptibility of the Jewish people to tuberculosis. In the old sections of the city, especially along the water front where the houses are old, and the races dwelling there susceptible to tuberculosis, the death rate is highest.

News Items.

Seventeenth French Congress of Medicine.—The Seventeenth French Congress of Medicine will meet at Bordeaux from September 27 to 29, 1923. The congress has already published the program for the scientific session.

American Urological Officers.—At the annual meeting of the American Urological Society held on May 21st to 23d at Rochester, Minn., the following officers for 1923-24 were elected: President, Dr. James A. Gardner, of Buffalo; vice-president, Dr. Herman L. Kreschmer, of Chicago; treasurer, Dr. James B. Cross, of Buffalo, and secretary, Dr. Homer G. Hamer, of Indianapolis.

American Otological Society Election.—The officers for the ensuing year of the American Otological Society are as follows: President, Dr. John B. Rae, New York; vice-president, Dr. D. Harold Walker, Boston, Mass.; secretary-treasurer, Dr. Thomas J. Harris, New York. The members of the council are: Dr. H. S. Birkett, Montreal, Canada; Dr. George Shambaugh, Chicago, Ill.; Dr. L. W. Dean, Iowa City, Ia.; Dr. J. G. Wilson, Chicago, Ill.

Laryngological, Rhinological, and Otological Society Officers.—The American Laryngological, Rhinological, and Otological Society has elected the following officers: President, Dr. Hanau W. Loeb, St. Louis, Mo.; vice-presidents, Dr. F. N. Sperry, New Haven, Conn.; Dr. T. E. Oertel, Augusta, Ga.; Dr. Ray Connor, Detroit, Mich.; Dr. T. E. Carmody, Denver, Colo.; Dr. E. R. Lewis, Los Angeles, Cal.; treasurer, Dr. E. W. Day, Pittsburgh, Pa.; secretary, Dr. W. H. Haskin, New York, and editor, Dr. G. L. Richards, Fall River, Mass. The board of directors voted to hold the next annual meeting in St. Louis, Mo., early in May, 1924.

Société Médicale de Geneva.—The centennial of this society was celebrated on May 12th. At the same time the pediatrists and radiologists of Switzerland held their national meetings in Geneva and joined in the celebration.

American Academy of Ophthalmology and Otolaryngology.—This organization will hold its twenty-eighth annual meeting in Washington, D. C., on October 16th to 18th. The guest of honor will be Sir William Lister, of London.

Society Election.—The Chicago Society of Internal Medicine at its eighth annual meeting elected the following officers for the ensuing year: President, Dr. Robert H. Babcock; vice-president, Dr. Solomon Strouse, and secretary-treasurer, Dr. Newell C. Gilbert.

New York Homeopathic Medical College Dinner.—The Alumni Association of the New York Homeopathic Medical College and Flower Hospital gave its annual dinner at the Hotel Pennsylvania, June 7th. About 175 members, including eighteen newly graduated interns, were present as well as many distinguished members of the medical profession. Senator Royal S. Copeland addressed the guests.

American Medical Association Annual Session.—Great preparations are being made for the next annual session of the American Medical Association which is to be held in San Francisco from June 25th to 29th. All the large hotels in San Francisco are reserving rooms for members of the association. Reservations on the "M. D. Special" of the Northern Pacific Railway are rapidly being made. Dr. A. W. Ide, of St. Paul, is arranging the tour and information relative to the plans can be obtained from him. His address is 914 Northern Pacific Building.

American Laryngological Association Officers.—The American Laryngological Association has elected the following officers for the ensuing year: President, Dr. J. Payson Clark, Boston, Mass.; first vice-president, Dr. Hubert Arrowsmith, Brooklyn, N. Y.; second vice-president, Dr. J. B. Greene, Asheville, N. C.; secretary, Dr. George M. Coates, Philadelphia, Pa.; treasurer, Dr. George Fetterolf, Philadelphia, Pa., and librarian, Dr. Joseph H. Bryan, Washington, D. C. The members of the council are: Dr. Norval H. Pierce, Chicago, Ill.; Dr. Harris P. Mosher, Boston, Mass.; Dr. Harmon Smith, New York, and Dr. Emil Mayer, New York.

American Gynecological Society Elects Officers.—At the annual meeting of the American Gynecological Society held at Hot Springs, Va., May 21st, 22nd, and 23rd, the following new officers were elected for the ensuing year: President, Dr. Barton Cooke Hirst, Philadelphia, Pa.; first vice-president, Dr. John Osborn Polak, Brooklyn, N. Y.; second vice-president, Dr. Herbert M. Little, Montreal, Canada; secretary, Dr. Arthur H. Curtis, Chicago, Ill.; treasurer, Dr. Charles C. Norris, Philadelphia, Pa. Other members of the council are: Dr. Robert L. Dickinson, New York; Dr. Walter W. Chipman, Montreal, Canada; Dr. George Gray Ward, New York; Dr. John A. Sampson, Albany, N. Y.; Dr. W. C. Danforth, Evanston, Ill., and Dr. Floyd E. Keene, Philadelphia, Pa.

Dr. W. J. Mayo Honored.—Dr. William J. Mayo, of Rochester, Minn., received the honorary degree of Doctor of Laws on June 11th from McGill University.

Health Statements to Be Discontinued.—The Office of the National Health Council at Washington, D. C., announces that the biweekly statements on national health legislation will be discontinued until Congress meets again.

Harvard University Appointments.—John H. Mueller, Ph. D., associate professor at Columbia University, has been appointed assistant professor of bacteriology at the Harvard University Medical School. Dr. Hilding Berglund has been appointed assistant professor of medicine.

Music Called Good Medicine.—A sixty day test with phonograph was completed in the wards of the New York Nursery and Child's Hospital. The test demonstrated that the waltz is good medicine and soothing. Well chosen music will now form part of the treatment of patients in that institution.

Cornell Medical Degrees.—Sixty-four students were graduated this year from the Cornell Medical College at the annual commencement exercises held in the college hall, First Avenue and Twenty-first Street. Dr. Livingston Farrand, president of Cornell University, made the address and awarded diplomas.

Jefferson Medical College Commencement.—The ninety-eighth annual commencement of Jefferson Medical College was held on June 1st. One hundred and forty-seven men received degrees; twenty-three members of the class received commissions as first lieutenants in the Medical Officers' Reserve Corps of the army.

Dedicate Jewish Hospital.—The Jewish Memorial Hospital at Dyckman Street and River Road was formally dedicated to the memory of soldiers, sailors, and marines who made the supreme sacrifice in the late war. Letters from President Harding, Vice-President Coolidge, Governor Smith, Theodore Roosevelt, Jr., General Pershing, and Herbert Hoover were read.

Health in New York State.—Dr. Edward S. Godfred, Jr., director of the Division of Communicable Diseases of the State Department of Health, has submitted to Commissioner Biggs a report showing the prevalence of the more important communicable diseases for the month of March and for the first three months of 1923, as compared with the same period for 1922 and with the average figures for the corresponding period during the last five years. Measles, scarlet fever and whooping cough are running high this year, while typhoid fever and diphtheria are materially lower. The scarlet fever this year seems to be of an especially mild type, only thirty deaths having been reported for the first two months out of 2,700 cases during the same period. In 1922, with almost precisely the same number of cases, there were fifty-four deaths. On the other hand, the fatality rates for typhoid fever and diphtheria have been higher; that for typhoid amounting to twenty per cent. of the reported cases and a little less than ten per cent. for diphtheria.

LONDON LETTER

(*From our own correspondent.*)

London, *April 6, 1923.*

PSYCHOLOGY IN INDUSTRY.

The annual meeting of the British National Institute of Industrial Psychology was held in the rooms of the Royal Society, London, a short time ago. The Earl of Balfour, in moving a resolution expressing the need for the application of the sciences of physiology and psychology to the improvement of occupational conditions, said it was one of his oldest beliefs that in Great Britain, in spite of the immense services rendered by British men of science to the great scientific work in which all the world should cooperate, they had as a nation underrated the great value of the work which science could do for society. The primary work of the institute was to make the labors of the wage earner easier, smoother, requiring less painful effort, leaving the pleasures of work, for there were pleasures of work, but as far as possible eliminating those other elements which too often intruded and made work a torture rather than a pleasure. Those were matters in which the psychology of industry must inevitably play a leading part, and it was extraordinary how much scientific method could do to eliminate effort which one would naturally think was intimately known to every employer and every worker who had to deal with industrial problems. They had only to glance through the reports of the institute to realize how much intelligent investigation and experiment could do to elicit the true laws that ought to govern physical effort in this or that particular industry. Science in their case had not fallen into the mistake of generalizations.

One of the directions in which intelligent effort was being pushed by the institute was to make such experimental investigations as would demonstrate what particular class of work should be most congenial and most successfully pursued by this or that candidate for employment. It did not treat all mankind as cast in the same mould, but it realized that there were individual differences between individual workers. It was of fundamental importance that scientific investigations should be made into the capabilities of the workers in the great industrial edifice in whose safety and ornamentation all were equally interested. Their labors touched the lives of all workers in the country, and they only touched those lives to improve and make them happier.

DANGEROUS DRUGS.

The Home Secretary has given notice recently that he has made new regulations under the Dangerous Drugs Act, 1920, amending the regulations already in force. These amending regulations come into effect forthwith. The chief alteration made is that doctors, dentists or veterinary surgeons, when giving prescriptions for dangerous drugs, are no longer required to sign the prescription with their full name. Instead it is provided that the prescriber shall sign with his usual signature, and, on the other hand, that a druggist shall only dispense a prescription for the drugs either if he is acquainted with the prescriber's signature and has no reason to doubt the genuineness of the prescription, or if he has taken reasonably adequate steps to satisfy himself that the prescription is genuine.

A REGULATION TO BE REVOKED.

It is announced that the Home Secretary proposes to make a regulation revoking that clause in the Dangerous Drugs Regulations which provides that a prescription for dangerous drugs may not be given for the use of the prescriber himself. In other words, a medical man will be able to order himself opium and cocaine as formerly. When the Home Secretary gave notice on October 7th of the regulation now to be revoked it was stated that the regulation which had the concurrence of the General Medical Council was made because several cases had recently been brought to his notice in which medical men who were victims of the drug habit procured considerable quantities of cocaine and morphine by giving prescriptions. It would not, it was added, affect a doctor's existing powers of procuring the drugs for use in the practice of his profession. In the House of Commons on February 28th, Sir Sydney Russell-Wells protested against the regulation, and urged the Government to withdraw it.

THE USE OF NONLETHAL GASES IN WARFARE.

There has just been issued from the press the volume of the medical history of the war dealing with gas warfare, in which it is stated that as the war went on nonlethal gas was widely used and it is hoped that in the next war the object will be to overcome or disable the enemy by these means rather than to kill him. It is interesting to note in the book that a destructive gas had not been discovered long before an antidote was found by chemistry so that, despite the statements often made with regard to the terrible effects to be expected from the gas warfare of the future, it seems that most of these alarmist statements may be discounted also.

HEALTH OF ROYAL AIR FORCE FOR 1921.

The health of the force in 1921 was better than in the previous year. India, however, showed a higher rate of sickness than in any locality in which the Force was stationed. There were more accidents in 1921 than in 1920, there having been 114 cases of injury and death in the former as compared with the latter year. Eighty cases occurred in Great Britain and thirty-four abroad. There were thirty-one deaths. Officers are medically examined once in each year. It was found at these examinations that 2,576 officers had flown 96,000 hours during the year. On the Eastern stations sand fly fever was the cause of a great deal of trouble. It is stated that as a result of researches carried out by R. A. F. bacteriologists at Malta a spirochete has been found similar to that isolated in hemorrhagic jaundice. A careful study was also made of glare and its effects on the eyes of pilots and it was discovered that ordinary tinted glasses are useless to prevent glare but special Crooke's glass U. B. and U. D. types were found satisfactory.

On April 2d last Inspector-General W. H. Lloyd, M. D., R. N., the oldest officer of his rank in the navy and the senior naval honorary surgeon to the King, died in London. William Harris Lloyd was born in Waterford, Ireland, in 1836, became a surgeon in the navy in 1856, and was on the active list for forty years. In August, 1862, when serving on the flagship Nile, in North America, he took charge of a number of yellow fever cases from the Rinaldo, and in the same month it happened that a death vacancy occurred in the sloop Peterel. In accordance with the custom of the service at that time, this vacancy was filled by a promotion on the station, and Dr. Lloyd became a staff surgeon. In May, 1866, he was appointed to the Jason in North American waters. His merits had now attracted attention and although he rose to the highest rank in his branch of the navy he never again served in a ship for ordinary medical duties. He served as secretary to the section of military surgeons at the International Congress of London in 1881, and represented the Admiralty in the same congress held in Washington in 1887. He retired from active service in September, 1896. In 1894 he was appointed an honorary surgeon to Queen Victoria, and from 1901 to 1910 respectively he was also an honorary surgeon to King Edward and King George.

VIENNA LETTER

(*From our own correspondent*)

VIENNA, *March* 30, 1923.

(*Concluded from page 705*)

The Medical Faculty has of late formed a peculiar habit, that of nagging at and belittling any progress in matters medical, *if made outside Vienna.* A few instances may be cited. In the course of a discussion on the therapy of ulcer of the stomach and duodenum, which went on for six weeks at the weekly meetings of the Vienna Medical Association, I was asked by Professor Eiselsberg to take part in the discussion. When I mentioned the real progress made in the United States by Sippy's treatment, nobody knew or had even heard the name of Sippy. One of the professors of stomach diseases, an internist, asked me if I meant "Mississippi," and thereupon pronounced the treatment as a mere modification of the well known old Leube treatment. He evidently never grasped the idea of thorough alkanization. And the eminent surgeon Eiselsberg thought they would certainly achieve success similar to that obtained by Sippy, if they only had enough milk in Vienna—but unfortunately they had none.

Here is another instance. The Surgical Clinic in Manchester reports a case in which respiration stopped during a cerebral operation, while the heart continued to beat for five hours, by means of artificial respiration. The doctors over here immediately recalled a similar incident that happened on one occasion when Billroth, assisted by Professors Salzer and Eiselsberg, operated on a young girl for struma. By continuing artificial respiration for six hours, the girl's life was saved. The case observed in England is therefore not the only one known, and perhaps "more patience in continuing the artificial respiration might have saved the patient's life."

There are about three thousand five hundred physicians in Vienna, scarcely one hundred of whom —I make this statement after having interviewed at least one hundred of them!—are in possession of a blood pressure instrument! Imagine such a state of affairs in the city in which lived Professor Basch, the originator of scientific blood pressure work. I have many times heard Professor Wenckebach lecture to his pupils, and in the postgraduate classes, on the absolute necessity of having a blood pressure apparatus. But it costs a fortune—twenty-five dollars! Compare with this our general practitioners, who carry in one pocket the stethoscope, in the other the Tycos. The physicians over here are ultraconservative, or rather so poor that they will not and cannot spend any money on new diagnostic or therapeutic instruments.

Most of the Viennese medical periodicals have had to reduce the size of their issues quite considerably, because of the high cost of paper and printing. In consequence of this reduced reading space there is very little opportunity for the few remaining scientific workers to have their articles published. The library of the medical association cannot even think of subscribing to the number of foreign medical periodicals it used to possess in prewar times; this accounts for the very inadequate information obtained by the physicians over here with regard to the medical and surgical progress of the Western nations, and also for their general lethargy and loss of idealism. Although this state of affairs has now lasted for years, the physicians and professors in Vienna consider it to be merely a temporary phase. It may be so—but I think it my duty to inform my colleagues in the United States of these conditions before they decide to spend their money on a rather nonremunerative trip to Vienna. Personally I do not believe that the medical Mecca of Vienna will ever celebrate its resurrection. It will share the fate of old Alexandria, Athens and Rome.

The constant effort to belittle the other fellow has become very obnoxious to me, as well as to many other Americans who relate numerous similar incidents from the various clinics. While I realize that the little fellow always tries to aggrandize his smallness by detracting from the merits of the big fellow, I consider this trait to be characteristic of the medical fraternity of Vienna precisely as it is characteristic of all the socalled intellectuals of Vienna; they always speak of their high culture, which nobody can take from them, of their greatest music centre, their great theatres, etc. They do not realize that their stage art has become the glorification of licentiousness, the chief problem dwelt upon being the sexual one; for fully eighty per cent. of their new plays are devoted to the Messalinan cult. The stage is, to a large extent, devoted to what we should term, in the United States, "indecency." I might mention dozens of plays—new pieces—which I have witnessed at the best play houses. There is the *Reigen,* written by the best connoisseur of Viennese life—Arthur Schnitzler; in it a woman, changing her sweethearts seven times, disappears behind a curtain for the purpose of cohabitation. Then there is the *Flamme,* by Hans Müller, a renowned author, which reveals the naked truth about the fast woman, the interior of a brothel and its workings on the open stage! The *Woman of Forty,* by Sil-Vara, is again a sexual problem. Or the new play *Es,* by the physician Schoenherr, in which only two persons, man and woman (physician and wife) debate on the stage, through the whole play, on the right of the tuberculous man to create children. He performs an abortion on his wife, and we even witness her awakening out of the anesthetic on the open stage!

It seems, in fact, well nigh impossible to go to a theatre without seeing sexual problems ventilated. In its drive against existing evils, the revolution also appears to have torn down the fences of decency and good manners. It is evidently the inherent duty of a revolutionary author—if he has any selfrespect at all—to express his thoughts indecently.

Under the false flag of socalled art, an absolutely naked woman—of rare beauty—performed dancing feats every night at what were formerly respectable playhouses, and many other instances might be quoted. A very influential part of the public criticizes this downfall of art mercilessly. They point out the fact that though many of these plays are called by harmless sounding names, even a cavalry sergeant might learn to blush on witnessing them. They demand stricter censorship. Literary or theatrical "booze," they argue, should no more be served to the public than alcoholic beverages are allowed to be served to juveniles—and so forth.

It took fully a month's agitation in the newspapers of Vienna before the chief of police had the naked woman dancer chased out of the city. Think of a "centre of culture" deliberating for more than a month before taking action against such a public nuisance! One theatre (Kammerspiele) gives nightly performances of the French trash work, *Le Jardin de Supplice* (the *Garden of Torture*), by Octave Mirabeau. In this play a woman artist (of some reputation!), Mrs. Konstantin by name, is seen lying on the floor of the open stage in libidinous convulsions, brought on by the horrible cries of a half naked man who is suffering agonies through having a red hot knife stuck into his spine! Not being able to produce a sufficient supply of theatrical rubbish of its own, Vienna has had to import French filth from Paris for the Viennese connoisseurs.

And yet I believe that a reform movement has set in of late in this general decadence. Two years ago about eighty per cent. of all the plays performed on the Viennese stage were devoted to sexual problems, while the percentage today does not attain fifty per cent. And why? Because the Social Democrats, when they came into political power two years ago, demanded the creation of the socalled *Kunststelle*, or art office. The latter buys outright fifty performances a year from the Burg Theatre, and twenty performances from the Grand Opera, both of which rank highest among the theatres and are subsidized by the government.

The art office pays to the theatre, two weeks in advance, twenty-five per cent. of the price the full house would average, the remainder being paid by the State. The same art office has made similar arrangements with other private theatres, but has to pay a higher price to them. In order to be able to meet this, it receives certain subsidies from the municipality out of the moneys the latter collects as luxury tax. This tax, amounting to sixty per cent. of the gate receipts taken at public entertainments, balls, dancing halls, barrooms, etc., enables the municipality to contribute a good deal to the money needed by the art office. Seats are distributed, by the art office, among the members of the five different political organizations and two private organizations, these comprising the employees of State and county and the members of most of the intellectual organizations (physicians, lawyers, university graduates, students and others). It is evident that these new poor, who constitute the standard bearers of the old civilization and culture, are thus enabled to obtain cheap seats at the theatres and to compel the managers to offer them good plays. One evening I chanced to drop into a theatre performance given for the benefit of the *Kunststelle*, and experienced a revelation. There were no low neck gowns, no shining solitaires in the boxes, but only humbly dressed, serious looking men and women, listening to a first class play at the expense of the profiteers, the standard bearers of depraved taste.

The art office also gets up philharmonic concerts and educational lectures for the benefit of the organizations it represents. It collaborates with the Ministry for Public Education, and it is certainly an institution well worthy of imitation in other countries.

The musical performances at the large music halls (Musikvereinssaal, Concerthaus, Staatsoper) seem to be the only culture left. It appeals to me, because I knew Vienna before it had acquired the earmarks of Sodom and Gomorrha, to be able to read such notices as one I recently saw. A Mozart, Schubert and Strauss evening to be given for the benefit of the "Help the Children" drive at the large Musikvereinssaal, etc.

Apart from this step in the right direction there is no romance left, no poetry—just outright, naked sensuality. And the Viennese places of popular amusement—the *kinos* (movies) are on a level with those we used to see in the United States ten years ago. Their funny shows are usually smutty stories, and it is a real treat to see some imported American humor or fun on the screen, not permeated by filthy thoughts. Their American bars, where society dances the shimmy and bathes in wine are, thank God, a thing of the past in America.

The picture of Europe, with its moral destitution, its noisy materialistic attitude, and its gaudy neglect of everything spiritual, poetical or romantic, needs no detailed description. Men imbued with better sensibilities and idealistic ambitions can hardly suppress their disgust and horror. The people of refinement explain this deterioration of good taste, on the stage, by the fact that the new rich, with their low grade of culture, constitute the bulk of theatregoers—and the theatres must cater to the taste of their patrons.

It would be unjust not to mention that there are a few public spirited men in this unutterably miserable city who call loudly for reform—a lonely call in the desert! A high government official, Kestranek by name, comes to the following conclusions after reviewing the Report of the American Committee for the Stoppage of Industrial Waste (*Neue Freie Presse,* January 5, 1923):

"On seeing the efforts of the said committee to utilize all possibilities for an increased output of work, the question suggests itself, What would that committee have said if it had investigated the conditions existing in *our* country? Over in the United States, in that great, rich country, every unnecessary movement of the hands, every second of time is scrupulously saved, whereas here, in this miserable, beggarly state, material as well as time and human strength is wasted. What would such a committee have reported if it had, for instance, studied our railroads and found loafing employees everywhere—numerous strong men, whose whole day's work consisted in punching tickets for an hour or two and wasting the rest of the day in playing cards? Or if it had found a vast number of strong men busying themselves exclusively with swinging little red flags to keep the public from crossing the rails, as if that same public, when out on the highways, needed guardians to save them from being run over by street cars or dashing autos?"

Kestranek closes his remarks by changing the words spoken by Goethe one hundred years ago, "America, you *are better off* than our old Continent!" into "America, you *are* better than our old Continent!"

The Medical Faculty of Vienna also realizes the need for revival. It tries with all its remaining might to regain its former lead in the world. They have established postgraduate courses of two weeks' duration at intervals of three months, to be attended by general practitioners. There are six to eight speakers each day, and every one of these speakers gives a synopsis of the subject chosen. To the man who follows medical literature sufficiently closely, it is a good recapitulation of things already known; but still I do not find much practical value in these theoretical dissertations, which any physician may read in his library without going to the trouble of making a special trip to Vienna. On listening to most of the men, I was often discouraged about the incompleteness of the lecture. I recall having once listened to a professor of surgery for two hours on the topic of treatment of wounds. At the end of the lecture I asked the professor if he had ever heard of Dakin's solution. "Oh, yes," he replied, rather embarrassed, "I really forgot to mention it!"

I have previously made the remark that the professors have become mercenary. You have all heard of mirion, the great iodine preparation; Professor Fröhlich, the pharmacologist, gave a lecture before the representative Viennese Medical Society on its merits. Professor Finger dwelt upon its excellent effects in syphilis, lupus erythematodes, etc. Many of those high merits have since been proved to be nonexistent, but some of the professors have invested the larger part of their savings in the manufacture of mirion. Under such circumstances we must not expect unbiassed opinions—especially not from Finger, who fought the introduction of salvarsan with all the means at his disposal years ago (a Jew, Ehrlich by name, was its originator, as we know) but has been using it at his clinic ever since. And Finger's assistant, Professor Kyrle, is now fighting Steinach's interstitial gland experiments with similar means.

Among some of the things which I find worthy of imitation is the recent institution of medical seminaries—weekly gatherings of general practitioners, at which two recognized authorities answer questions that are put to them beforehand either in writing or by telephone. Every evening is devoted to one specialty, and the speaker must be prepared to answer every question in an up to date fashion. The educational value for the general practitioner is far greater than that derived from postgraduate courses, if he attended them, because the latter take in far too limited a field of medicine and then dwell too broadly on those limited fields. The originator of this Seminary of the College of Viennese Physicians, Professor Biehl, is seconded by its secretary, Dr. Flesch, in making every effort to render these gatherings a success. And judging by the large number of physicians attending them, they certainly are a success. Until now, evenings have been devoted to questions pertaining to internal medicine, surgery, gynecology, pediatrics, dermatology, urology, physical therapy, neurology, tuberculosis, x ray treatment, psychotherapy, orthopedics, ear, nose and throat diseases, etc.

This same idea is carried out in *Ars Medici*, a medical paper of international circulation; it contains a section on questions, put by general practitioners, and answers given by recognized authorities on the subject. It was for this reason that I have promoted the English edition of *Ars Medici* for our American confrères.

For more than two years I attended the weekly meetings of the Viennese Aerztegesellschaft (Medical Society of Vienna) closely and conscientiously. Once I went to Prague, and attended the weekly medical meeting of the German Society. The scientific standard held by Prague is, in my opinion, higher by far than that in Vienna. The Viennese Medical Faculty—to judge by the fifty per cent. of the students coming from the Balkan States and Eastern Europe—may be all right and good enough as a medical centre for those less civilized nations, but it surely can no longer aspire to be the medical mecca of the Western nations.

I have no doubt that all this may seem somewhat scathing, and that I shall find a great many objectors. I have stated the truth as I saw it, and have nothing to fear, nothing to gain by what I have said. I realize that a good number of the physicians who come over here from the United States do so merely for the purpose of getting a diploma from the Vienna University, in the belief that it will draw a certain crowd to their home offices. I know, from my close association with the American Medical Association of Vienna, that many of these diploma chasers have spent but a few weeks in the respective clinics, but diplomas were given to them provided they paid the fee—a thing which was not possible in prewar times, until at least six months' clinical courses had been attended. But poverty has compelled the university to be lenient.

Most of the American doctors who have been in Vienna will, in their hearts, admit that my remarks are correct. They will not dare to make the statement loudly, however, because they would lose, by so doing, something for which they have paid dearly—the nimbus of having been in Vienna. Most doctors scold and cuss a great deal, while over here, but they keep silent as to the inferiority of things medical in Vienna, as soon as they reach home soil. Any physician who really wants to learn something does not need the Vienna finish; there are plenty of excellent postgraduate schools in America. I shall never forget the wonderful impressions I took with me from clinics like those of the Mayos, Crile, Bloodgood, Finney and dozens more!

The fact that physical decadence causes mental decadence has been brought home to me quite intensely here in Vienna.

Book Reviews

FUNCTIONAL ALBUMINURIA AND NEPHRITIS

Die funktionelle Albuminurie und Nephritis im Kindersalter. Von Professor Dr. Ludwig Jehle. Wien, Leipzig und München: Rikola Verlag, 1923. Pp. 68.

The pathologicoanatomical and clinical questions associated with albuminuria are manifold and difficult to determine definitely because of the different terms and classifications used and the divergence between the clinical appearance and the pathological anatomy of the disease. The extrarenal factors (vasomotor, neuropathic and mechanical) also tend to complicate matters. In addition, there is also a peculiar predisposition and an abnormal body constitution, which influence the clinical appearance of renal disorders. The condition may be malignant, may show an indeterminable etiology, and cause difficulty in making the diagnosis and in instituting the proper treatment in infancy. The treatment cannot be determined by any one symptom, but should be directed against the entire symptom complex. The symptoms of a local renal injury should be differentiated from those caused by extrarenal factors or by the affection of the entire organism. The character of the renal injury is determined by uranalysis and the renal functional tests, whereas the other organic injuries require a thorough clinical examination.

The diseases of the urinary organs are divided into orthostatic—lordotic albuminuria, functional nephritis and renal diseases. A special chapter deals with acute nephritis (glomerulonephritis), chronic nephritis, the nephroses, the therapy of renal diseases. syphilis of the kidney, hypernephroma, paroxysmal hemoglobinuria, and tuberculosis of the kidney. Cystitis and bacteriuria are considered as well.

LOCAL ANESTHESIA

Practical Local Anesthesia and Its Surgical Technic. By Robert Emmett Farr, F.A.C.S., Minneapolis, Minn. Illustrated with 219 Engravings and Sixteen Plates. Philadelphia and New York: Lea & Febiger, 1923. Pp. xviii, 529.

This very latest book presents the author's personal observations and the experience of twenty years in local anesthesia. The technic of the various methods of securing local and regional anesthesia (except spinal anesthesia) and their advantages are described in great detail. The illustrations and actual photographs are very numerous and a number of case reports are cited. The first part of the book deals with certain problems in connection with anesthesia, including the equipment and surgical technic. Great stress is naturally laid upon the anatomy of the sensory nervous system. Regional anesthesia and the different operations that may be carried out with it are described in full. The necessity of teamwork on the part of the assistants and the importance of considering the psychic factor of the patient receive special consideration. The proper technic in the induction of local anesthesia requires perfection in the anatomical, surgical and psychic elements to achieve success. Additional accessories in the form of improved instruments, technic and necessary aids are also mentioned. These are distinct advances in the art of local anesthesia, that have come to stay, inasmuch as they have proved their worth. Every conceivable angle of local anesthesia, both from the surgeon's and patient's standpoints, are taken up. No one who professes to be an up to date surgeon can afford to be without this valuable and epoch making volume. It contains much that can be found nowhere else.

HEMATOLOGY

Hematology in General Practice. By A. Knyvett Gordon, M.B., B.C., B.A., Cantab. New York: William Wood & Co., 1923.

This little book is primarily intended as a guide to the general practitioner. It is by no means an elementary textbook of hematology. Its chief emphasis is on a "rough examination of a stained blood film." The author states that the accurate counting of the total number of red or white cells is usually unnecessary. The book contains a number of generalizations that are unfortunate and a number of case histories that are unconvincing. The theoretical basis for the vaccine treatment that he recommends is unsound. Thus, because a patient showed a very slight leucocytosis, cocci were sought for in the stool and eventually found, a vaccine was prepared and the patient was cured in three months. On page 38 the author describes a case of anemia with a count of 7,000,000 red blood cells and a hemoglobin of eighty per cent.

The book is of little value and to an uncritical reader will do more harm than good.

DUFF HOUSE

Duff House Papers. Edited by Edmund I. Spriggs, M.D., F.R.C.P. Volume One. Illustrated by 190 Figures, Six Charts and One Colored Plate. Oxford Medical Publications. London: Henry Frowde and Hodder & Stoughton, 1923. Pp. x, 387.

This report contains many articles by various authors and includes some of the work done since the opening of Duff House in 1913, which is now collected and published in book form. These articles appeared in *The Quarterly Journal of Medicine,* the *Lancet,* the *British Medical Journal,* the *Proceedings of the Royal Society of Medicine,* and the *British Journal of Surgery.* The article Food and How to Save It was published by the Ministry of Food. The new material includes a manual for diabetic patients and is intended for the information of the diabetic who is thus enabled to cooperate with the physician in the treatment. It teaches the patient how to examine the urine and how to select and prepare his diet. It is very practical in scope. There are also chapters on diabetic cooking and special gardening, written by specialists. About half of the book is devoted to a detailed account of the x ray technic employed at Duff House for examination of the alimentary canal. The röntgenograms are very numerous, clear and illuminating and may well serve as a röntgenological atlas of the alimentary canal. This book should prove most interesting to the gastroenterologist, metabolist and röntgenologist. Like most of the Oxford medical publications, this report is a beautiful example of the bookmaker's art.

DEAR BRUTUS

The Plays of J. M. Barrie. Dear Brutus, A Comedy in Three Acts. New York: Charles Scribner's Sons, 1922. Pp. 140.

Old familiar friends appear in a garb fresh and dainty yet sober in this edition of Barrie's works. Yet these friends are none too familiar, for many of them have passed over our stage and gone until thus revived for closer and more lasting companionship. *Dear Brutus* has all of Barrie's charming grace whereby he comes close to that intermingling of comedy and tragedy which makes up human life. The play presents Lob, a little being immeasurably old and yet ever young, from the core of life itself. This wight has read the secrets in the lives of the friends gathered about him. Wistful yet fearful he sends them into the wood of dreams where they may read the secrets themselves that those "who have the grit in them" may shape their lives anew. Barrie's skilful use of the dream mechanism is but a part of the subtle intuitive psychology with which the entire play is prepared for the stage or for private reading.

Medicoliterary Notes.

A new volume of essays by G. K. Chesterton is to be published shortly by Dodd, Mead & Co. It will bear the title *Fancies Versus Facts,* and will deal with all sorts of things, from lawyers to cavemen, and from psychoanalysis to free verse.—*New York Times.*

* * *

Children Astray is the title of a volume by Saul Drucker and M. B. Hexter to be issued in the near future by the Harvard University Press. It consists of a collection of case studies of the delinquent children and their successful care and treatment in an institution for orphans.

* * *

Robert Keable, author of *Simon Called Peter* and of *The Mother of All Living,* is reported to have gone to the island of Papeete, Tahiti, where he is living in the house that originally belonged to the artist, Paul Gauguin, and working on a new novel.

* * *

During the year 1922 rats to the number of 21,590 were destroyed in Greater New York through the efforts of an antirat campaign planned to rid the water front, warehouses, markets, restaurants, and other places where foodstuffs are handled and sold, of these dangerous pests. In this connection it is of interest to quote briefly from a recent report of the British Incorporated Vermin Repression Society, in which it is estimated that Great Britain's rats cost her forty-two pounds a minute. "A method of rat repression that has met with considerable success in recent years is one based on the method devised by Rodier for the reduction of the large rabbit population in Australia. Rodier killed all the does he could capture, but the bucks he released. There are certain resemblances between rabbits and rats from which it might be expected that this method . . . would succeed in the case of rats. In both cases the males are in excess, the usual proportion in the case of rats being ten males to three females. The fathers in both cases show a tendency to eat their offspring, especially when the proportion of males is increased. Thus Rodier's method, by encouraging cannibalism and by forcing the females to compete for their food supply with an excess of vigorous males, is a powerful deterrent to successful breeding."

* * *

A comparative study of the reath rate in thirty-four states of the health registration area, including eighty-two per cent. of the country's population, made by the Census Bureau, shows that New York State alone has a mortality of 21.8 in each hundred thousand of its population. This compares with 16.6 in each hundred thousand of the total public in this area.—*New York Medical Week.*

The Illinois Society for Mental Hygiene has begun recently the publication of an interesting little sheet called the *Mental Health Bulletin.* It will be a monthly except that no numbers for July and August will be issued. The statement is made in the first number that the *Bulletin* will serve as a medium through which the activities of the Illinois Society for Mental Hygiene will be more intimately conveyed to members and others interested, and that it will contain "useful and reliable information on important aspects of mental hygiene, as well as news of interest. It is hoped especially to have the *Bulletin* reach teachers, clergymen, jurists, probation officers, social workers, nurses, physicians, state and local officials, and others who come in contact with groups of children and adults."

* * *

A recent number of the *American Journal of Public Health* contains an entertaining editorial on Fads in Medicine. Among those described is Bishop Berkeley's tar water, a mixture of a quart of tar and a gallon of water, reputed to be useful in many ailments of man and animals to relieve "tender nerves and low spirits, to improve children, and to relieve the British people of a tendency to "grow stupid or doat sooner than other people." Another of these miraculous fads was Dr. Elisha Perkin's metallic tractors, consisting of two pieces of metal about three inches long, blunt at one end, and sloping to a point at the other. These were patented and soon attained a remarkable popularity, not only in England, but in Europe and America. The tractors were used to "extract" from human bodies in a few moments the most violent pains. The son of the inventor in a few years saved more than ten thousand pounds from the proceeds of their sale in Great Britain alone. No wonder Couéism is successful!

* * *

Mr. Clifford W. Beers, secretary of the National Committee for Mental Hygiene, and author of *A Mind That Found Itself,* sailed recently to attend a mental hygiene conference to be held in Paris.

* * *

A bill which would prohibit the use of white lead and sulphate of lead in the internal painting of buildings, with certain exceptions, has been recommended by the Third International Labor Conference of the League of Nations, and is being prepared by the Belgian Ministry of Labor. The Municipal Council of Liège has adopted resolutions prohibiting the use of white lead in inside and outside painting work done for the municipality.—*Lancet* (London).

Practical Therapeutics

PAIN AND ITS TREATMENT IN THROMBOANGITIS OBLITERANS*

By Charles Goodman, M. D., F. A. C. S.,
and
Julius Gottesman, M. D.,
New York.

Pain, the predominating symptom in thromboangitis obliterans, is of the greatest concern to both the doctor and the patient in so far as it does not readily respond to the usual forms of treatment. The severity of the pain and the danger attendant upon the continued use of morphine and its derivatives necessary for its alleviation, is too well known to occasion further comment. We know of no symptom complex in which more methods have been tried for the relief of this predominating symptom.

The many brilliant results reported by various observers obtained in chronic inflammatory joint conditions with foreign protein injections, suggested to one of us (Goodman), the possibility of this form of treatment in thromboangitis obliterans.

The commonly accepted view of thromboangitis obliterans is, that it is a chronic inflammatory process beginning in the peripheral bloodvessels, the resulting symptoms and physical signs depending upon the loss of circulation in the affected parts. We assumed that the same theoretical considerations that bring about relief in chronic inflammatory joint conditions might obtain in thromboangitis obliterans.

With this object in view a group of definitely proved cases of thromboangitis obliterans was selected from the surgical service of the Montefiore Hospital. The cases, four in number, had had amputations at various times with pathological confirmation of the clinical diagnosis. The most pronounced symptom in all of them at the beginning of this investigation was severe pain, necessitating heroic medication with morphine or its derivatives, at most times ineffective. To this group another case of clinically observed thromboangitis obliterans of eight months' duration was subsequently added.

The plan followed was as follows: A series of injections of the stock typhoid vaccine distributed by the New York Board of Health was given, beginning with the minimum dose sufficient to produce a mild reaction (temperature, pulse, malaise, joint and bone aches and pains). Typhoid vaccine was decided upon because of its convenience, its relative safety and the ease with which it could be administered. Intramuscular doses were given at weekly intervals, gradually increasing the dose at each injection sufficient to produce mild symptomatic reaction.

The most striking result obtained was the sustained relief of pain in all cases, sufficiently complete to obviate any further necessity for medication with morphine or its derivatives. In one instance, Case II, there was a return of pain because of onset of gangrene in the toe. All the cases are still under observation.

Case I.—N. G., Russian, tailor, admitted May 14, 1921. The chief complaint was pain in the left hand. One sister had had Raynaud's disease. The disease began seven years ago with itching sensation and pain in right middle index finger. A year and a half later the tips of the left toes became cold, followed in two months by gangrene. Amputation of left lower extremity was done two months later. The right leg was amputated one year later because of pain.

Physical examination showed the left lower extremity amputated through the middle of the thigh, the right leg amputated through junction of upper and middle thirds of leg. Left hand bluish and cyanotic; skin of fingers glossy and thinned. Left radial pulse smaller than right. During the patient's stay in the hospital he complained of constant pain in the left hand. On November 9, 1921, there had been no relief from any form of treatment. On December 10, 1921, a series of intramuscular typhoid injections was begun, starting with one quarter c. c. The injections were continued at weekly intervals until March 17, 1922, the largest dose being two c. c. The pains in left arm were entirely checked, and have continued so to date.

Case II.—A. G., Russian, aged fifty-four, peddler. The chief complaint was pain in the left foot. The trouble began fifteen years ago with pain in the big toes, first right and then left. Gangrene began to develop, and was checked by baking. There had been more or less pain on and off for fifteen years. On April 21, 1921, the right leg was amputated because of severe pain. He was admitted to the hospital because of pain in the left foot.

The physical examination showed the right lower extremity had been amputated through the lower third of the thigh. The left foot was swollen and cyanotic. Neither the popliteal, dorsalis pedis or anterior or posterior tibial arteries could be felt. Because of the intensity of the pain, a series of subcutaneous injections with Ringer's solution, starting December 3, 1921, were given. No relief was obtained. On January 19, 1922, typhoid injections were begun, starting with one half c. c. Injections were continued until March 17, 1922, with relief of pain. The patient was entirely free from any pain until in the early part of January, 1916, pain developed following an accidental cut with a pair of nail scissors. The gangrene spread so rapidly that the extremity had to be amputated.

Case III.—D. S., Russian, aged forty-nine, furrier, admitted June 17, 1921. The chief complaint was pain in the right hand and right stump. The present illness began in 1910, with a feeling of fatigue in both arms and legs following exertion. During the summer of 1911 he began to experience numbness in the toe of the left foot and heel of right foot. Two years after the onset there developed sharp continuous pain and sensation of coldness in the outer part of the left foot. In March, 1913, a left arteriovenous anastomosis was performed without relief from the pain, followed by an amputation through the left thigh, in April, 1913. One

---

*From the Surgical Service of Montefiore Hospital, New York City. Received for publication on September 22, 1922.

year later there developed pain in the right middle and index fingers and right big toe. Under treatment with hypodermoclysis the condition subsided. During the early part of January, 1913, pain developed in the right toe, with gangrenous sloughing. The pain continued in the right toes until October, 1919, when the right extremity was amputated through the lower third of the leg. January, 1921, an ulceration developed of the right stump, with severe pain around the ulceration.

The physical examination showed the left lower extremity amputated through the middle of the thigh; right extremity through lower third of leg. The left radial pulse was smaller than right. Because of the severe pain and developing gangrene in the right stump, amputation was performed August 12, 1922, through the lower third of the thigh. September 1st the patient began to complain of pain in the fingers of the left hand, sufficiently severe to require constant medication with morphine. On December 17, 1921, a series of typhoid injections was begun and continued until March 17, 1922, the largest dose being one and three quarters c. c. The pains steadily diminished and the patient has been free from pain to date.[1]

We do not understand as yet just how foreign protein injection brings about this relief from pain; whether the protein acts by producing an inflammatory reaction in the bloodvessel sufficient to diminish the existing thrombus or whether it mitigates the vascular spasm, are theoretical possibilities. Suffice it to say that the results obtained are sufficiently encouraging to warrant the further use and observation of this form of medication. All the cases cited above are still under observation.

It is hoped that this tentative report will encourage other observers to test the merits of protein injections in this condition, so that sufficient data may be obtained to determine the real merit of this form of therapy.

266 West End Avenue.
129 East Sixty-ninth Street.

Management of Diphtheria. — E. Charles Fleischner and Edward B. Shaw (*Medical Clinics of North America,* September, 1922) call attention to the following important diagnostic points which are characteristic of diphtheria: 1, a tonsillar exudate that spreads beyond the tonsil; 2, any exudate in the throat associated with aphonia, hoarseness and laryngeal cough; 3, progressive aphonia, hoarseness and laryngeal cough without exudate; 4, a sanguineopurulent or sanguineous discharge from the nose, with or without a membrane, but associated with toxemia; 5, all doubtful cases should be considered as cases of diphtheria as regards treatment, especially in the presence of pronounced signs of intoxication. The taking of smears from the exudate must not be neglected, as often a diagnosis may be made immediately. The important points in the differential diagnosis are: 1, quinsy occurs rarely in children; 2, peritonsillar abscess is usually unilateral; 3, the edema and swelling develop more rapidly in severe diphtheria than in peritonsillar abscess; 4, the exudate spreads to the pharynx or palate in diphtheria; 5, a peritonsillar abscess either follows follicular tonsillitis or it starts in the deep tissues around the tonsil, pushing it forward; 6, quinsy is more painful; and, 7, severe diphtheritic swelling and edema usually marked swelling of the regional lymph nodes and periglandular edema, which is rare in peritonsillar abscess.

In treatment, single large doses of antitoxin are preferable to repeated smaller injections. The intravenous route is the best except in, 1, status lymphaticus; 2, hypersensitiveness to horse serum (anaphylaxis), in the presence of which, as shown by the history and the intracutaneous test, the patient should be desensitized; 3, patients showing an unusual colloid reaction. Intramuscular injections may be given in mild cases, but severe cases require intravenous therapy. The dose of the antitoxin should be gauged by the age of the patient and the severity of the disease. If the first injection is insufficient, a second dose should be given. Absolute rest in bed is necessary and the process of getting up from bed should be gradual. Morphine or codeine hypodermically, or opium suppositories are useful in mental excitement and in early cases of myocardial degeneration. Local treatment is indicated in, 1, excessive pain in the throat; 2, mechanical obstruction, especially in the nose, and 3, laryngeal involvement, for which purpose hot saline irrigations are advisable. Frequent uranalyses aid in determining the prognosis.

The Treatment and Prognosis of Leprosy.— P. Harper (*British Medical Journal,* July 8, 1922) advocates the intravenous injection of crude chaulmoogra oil, sterilized by heat. He says that from five to fifteen minims of the oil at body temperature are injected once, twice, or three times daily. His plan is to give a fortnight's rest at the end of each four weeks' injections. The treatment is maintained until a treatment reaction occurs, when it is stopped until the reaction is over. He used to give the oil intravenously in a mixture with ether and iodine, or carbolic, but found the crude oil as above to be more satisfactory. During the last two years 35,000 intravenous injections of chaulmoogra oil have been given at Makogai. Syphilis, compensated heart disease, tuberculosis, and the filarial diseases are not necessarily contraindications. In cases of albuminuria without casts the albuminuria is lost during treatment with this method. Chaulmoogra oil was first given intravenously by Verham, Stevenel, and Noc. They gave it in fine emulsion; but their doses were very small, being about one hundredth to one fortieth of the doses given by the author. Nevertheless they obtained good results. Chaulmoogra oil is so unpleasant to take by mouth or subcutaneously that for years efforts have been made to find an unirritating active principle. One of the earliest of these was antileprol, rediscovered recently and much praised as the ethyl esters or Dean derivates by the Hawaiian leprologists. Another rediscovery is Sir Leonard Rogers's sodium hydnocarpate and gynocardate, the sodium salts of hydnocarpic and gynocardic acids, which were used twenty years ago by Roux. These derivatives of chaulmoogra oil seem to act in precisely the same way as the oil itself, over which they possess no real advantage.

---

[1] A report of Cases IV and V will appear in the author's reprint.

Abstracts from Current Literature

SYPHILIS AND ITS TREATMENT.

Early Diagnosis and Treatment of Syphilis.—K. Ullman (*Wiener klinische Wochenschrift,* December 7, 1922), discusses very thoroughly the difficulties of the early diagnosis of syphilis, especially with extragenital primary lesions. The proper technic in the procuring of the material and of the method of its examination are very important in the search for spirochetes. The best results are secured with the dark field examination of the fresh, unstained specimen. The light dark field condenser is dispensable for the general practitioner. A negative finding gives no definite information. Gland puncture may give some valuable aid. Inasmuch as the Wassermann reaction is negative during the first six weeks, it is unavailable for the diagnosis of syphilis during that time, but it is important in the determination of whether or not the infection has become generalized in the organism. In seronegative syphilis, cures may be achieved in one hundred per cent. of the cases with a powerful combined course of neosalvarsan and mercury or a simple course of neosalvarsan treatment. The author emphasizes the importance of examining all suspicious lesions for the presence of spirochetes. The induration of the base of the lesion may be absent, especially if the seat of the lesion is atypical.

Syphilitic Aortitis.—Eugene Sterling Kilgore (*Medical Clinics of North America,* September, 1922) reports some of the less common types of pain encountered in syphilitic aortitis—sharp effort pain in the back, pain in the upper left quadrant, and darting epigastric pain on lifting. There may also be early heart symptoms even in the absence of pain and also vague gastric symptoms. The signs of aortic regurgitation usually appear suddenly in the absence of a complicating mitral disease. Aortic stenosis is rare. Saccular aneurysm, a late manifestation, may be painless and devoid of the usual signs. The earliest physical signs depend upon the stretching, thickening and stiffening of the aortic wall, including such signs as dilatation of the veins of the neck or the pulsation of tortuous carotids, prominent subclavian and suprasternal pulsation with upward cardiac displacement; also inequality of the carotid pulsations, tenderness in the suprasternal notch, pulsation beside the manubrium, especially on the right side and dullness over and beside the upper part of the sternum. Aside from the diastolic aortic regurgitant murmur, the most important auscultatory sign is the modified second aortic sound (*le bruit de tabourka*). Fever is uncommon. Earlier lesions may be demonstrated by the x rays, which should be used in every case. The röntgenogram shows simple bulging of the ascending limb of the aortic arch to the right of the sternum, just above the curve of the right auricle on the two meter plate. The Wassermann reaction is positive in sixty to ninety-five per cent. of the cases. Life may be prolonged with the proper treatment and the author believes that intensive arsenical treatment is justified. The antisyphilitic treatment is begun with mercury, which is followed by minimal doses of neosalvarsan (0.2 gram), gradually increased at five day intervals up to 0.9 gram. After a month of salvarsan treatment, mercury is again given by inunctions or injections for a month, alternating in this way every month for six months. A period of rest is then given for six months, which is then followed by another course of six months' treatment, after which the patient is kept under observation without further treatment unless it is specially indicated. Potassium iodide in small or moderate doses is given during the periods of other treatment.

Cellular Blood Reaction and Individualizing Treatment of Syphilis.—As a result of his experiments, J. Kyrle (*Wiener klinische Wochenschrift,* October 19, 1922), asserts that the adequate aid of the organism is of the greatest significance in the final result in every therapeutic procedure in advanced syphilis and that we can estimate to a certain extent the reacting power of the organism by the form of the reaction of the blood picture. He found that the individual differences in the cellular reaction of the blood in syphilis and in the antisyphilitic procedures are by no means slight and that in individual cases timely variations in the capacity for reaction play an important part. The appearance or absence of leucocytosis in connection with a certain therapeutic procedure should be considered as evidence to show whether that particular organism is in a state of favorable or unfavorable resistance toward the infecting agent or not. Kyrle also found that a comparatively mild treatment is sufficient in cases with a primary leucocytosis, or those in which there is strong reaction to injections of sodium nucleinate or similar remedies. Some cases of syphilis react to every specific or nonspecific treatment with a leucocytosis, others react only at the beginning of the treatment, while others do not react at all. This capacity of reacting seems to correspond with the therapeutic result and it also seems proper to take this phase of reaction into consideration when administering specific remedies and to refrain from such treatment in the presence of a leucocytosis.

Syphilis and Its Visceral Manifestations.—L. B. Cowen (*American Medicine,* June, 1922) makes the following pertinent statements regarding syphilis and its visceral manifestations: When it is recalled that syphilis, almost from its inception, is a septicemia, the source of entrance of the organism into the blood being the initial lesion, it is not hard to understand its remarkable and variable symptoms and lesions. It is known that a general septicemia exists at least three or four weeks before secondary lesions appear. The lesions of syphilis, unlike those of tuberculosis which they resemble remarkably, do not progress indefinitely. Both local and general acquired immunity play an active part in limiting the growth of the organisms and the development of the lesions. Wile's classification of the disease into early and late syphilis depends upon the fact that the lesions of early syphilis are superficial, with no serious interference of function, while those of late syphilis are deep, tend to undergo ulceration and necrosis, with serious interference of function in vital organs. The viceropathies of early syphilis give few subjective symptoms, although spirochetes are present in every viscus. When the roseola is on the skin, a similar condition is present in the viscera, as has been shown at autopsy. Syphilitic aortic insufficiency causes less hypertrophy of the left ventricle than endocarditis, because the coronary arteries are affected in the former, giving the heart muscle less nourishment. Angina pectoris is often due to syphilis of the coronary arteries. In late gastric syphilis there may occur a catarrh, round ulcer, submucous gumma, diffuse infiltration and cicatrices. In specific ulcer there is usually a diminished acidity, instead of an increased acidity which is found in nonspecific ulcer. Most cases react well to antisyphilitic treatment. Syphilis should be considered carefully in all cases of rectal disease. It should be ruled out in all cases of fistula in ano, ischiorectal abscess, ulcerations about the rectum, as well as in all cases of suspected carcinoma and tuberculosis.

Local Wassermann Reaction in the Early Diagnosis of Primary Syphilis.—D. Stern and Harold Rypins (*Journal of Laboratory and Clinical Medicine,* November, 1922) recommend the use of the local Wassermann reaction carried out on the surface serum of a suspected primary lesion as a practical and valuable aid in the early diagnosis of primary syphilis. Where no dark field microscope is available, or where the spirochetes are not found, or a lesion has been treated with a spirocheticide, the local Wassermann test as an additional means of diagnosing primary chancre may establish the diagnosis before the blood becomes positive. Thirty-four cases of demonstrated primary chancre and two with proved nonluetic lesions were studied. The Wassermann test on the chancre sera of the thirty-four cases was positive in all instances. The majority of these patients at the time the local Wassermann was done gave negative blood tests, and had no secondary manifestations. In all cases 0.0125 c. c. of the serum and in some cases only 0.004 c. c. was sufficient to give the positive result. The authors found that local treatment of the lesions with a spirocheticide apparently had no effect on the complementfixing bodies, though the spirochetes may disappear.

Arsenical Preparations in the Treatment of Syphilis.—Abr. L. Wolbarst (*International Journal of Surgery,* June, 1922) states that a recent investigation made by a committee of German physicians showed that the chance of fatal result in a properly given injection is about one in 13,000 with old salvarsan, one in 20,000 with sodium salvarsan, and one in 162,800 with neosalvarsan, an average of one fatality in 56,445 injections. Many physicians today believe that in the various refining processes salvarsan has lost in antiluetic potency. On the other hand, some believe that the drug has not lost any of its power, but that the treponema has developed strains that are resistant to arsenic and therefore to arsphenamine medication. Obviously it is impossible to offer positive proof on either side of this question, but the fact remains that we do not get the results with one injection of arsphenamine today that a similar dose effected in 1910 or 1911. Of the six methods of injection, i. e., intravenous, intramuscular, subcutaneous, oral, rectal, and intraspinous, the intravenous is best for routine therapy. It has been the practice of the author for the last seven or eight years to protect his patients against possible recurrence in such cases by advising a form of insurance that has been very satisfactory in his experience. The insurance consists of neoarsphenamine injections administered three or four times a year, especially in cases in which there is a fear of neurorecurrence. The author states that there has not been a single recurrence of any kind in any patient who has taken this insurance systematically. In concluding, Dr. Wolbarst reminds us that the two remedies, arsphenamine and mercury, are powerful poisons and that caution must be taken to consider possible susceptibility or idiosyncrasy.

Treatment of Syphilis with Trépol.—Rudolf Rosner (*Wiener klinische Wochenschrift,* November 23, 1922), states that the French bismuth preparation trépol produces a prompt symptomatic effect. The spirochetes disappear after forty-eight to seventy-two hours (in contrast to a period of twenty-four hours with salvarsan). The effect on the Wassermann reaction is slower than that with salvarsan. A Herxheimer reaction was observed in twenty-five per cent. of cases of secondary syphilis. All of the patients showed a slight bismuth stomatitis; intestinal symptoms occurred comparatively often; frequently there were also slight injuries of the kidneys (cylindruria). In more than half of the cases treated a leucocytosis was found after the injection, which was not followed by any reaction; rises of temperature are rare as is also the loss of weight.

Syphilitic Serum Reactions.—K. Taoka (*Japan Medical World,* May 15, 1922) draws the following conclusions from his experiments: The specific substance for Wassermann reaction in syphilitic serum is carried away with the flakes of Sachs-Georgi's reaction in a certain ratio. By the removal of the flakes from the syphilitic serum, the remaining serum becomes negative to Wassermann's and Sachs-Georgi's reaction tests.

The flakes of Sachs-Georgi's reaction are dissolved by fresh serum or alkaline solution.

The flakes of Sachs-Georgi's reaction combine with complements.

The ability of the flakes of Sachs-Georgi's reaction to combine with complements.is destroyed by a concentration above n/100 of alkaline or a concentration above n/100 of alkaline or n/400 of acid. The resistance of the flakes against the ions is the same as that of the syphilitic reactive substance of a serum.

The flakes of Sachs-Georgi's reaction can be divided into ether soluble and non-soluble parts.

When the antigen is added to the nonsoluble part it gives the specific Wassermann and Sachs-Georgi's reactions. Thus it corresponds to the syphilitic reactive substance of the serum. As far as tested, it did not give albumin reactions.

The ether soluble part is composed of sufficiently active antigen.

Each part, which was separated and became comparatively pure, can be recombined and gives a specific reaction.

When the serum globulin is precipitated by 33 of the saturation percentage of ammoniacal sulphate solution, the syphilitic reactive substance is almost entirely removed into the precipitate. Only a part of it is removed with the globulin precipitated by the other methods.

When a syphilitic serum is heated the Wassermann reaction is weakened, but Sachs-Georgi's reaction, on the other hand, is strengthened.

The Sachs-Georgi's reaction is strengthened by the removal of a part of globulin of an unheated syphilitic serum.

Globulin separated from an unheated serum either syphilitic or nonsyphilitic, has a strong anticomplemental action in the Wassermann reaction. This action of the globulin is destroyed by heating it before or after the separation. It is thermolabile.

The weakening of the Wassermann reaction by heating a serum is not due to the destruction of the reactive substance, but due to the disappearance of the anticomplemental action of globulin.

The Wassermann reaction with an unheated serum is liable to give a nonspecific positive reaction.

An unheated globulin prevents the precipitation in the Sachs-Georgi's reaction. This preventive action is destroyed by heating. It is thermolabile.

The reason why an unheated serum does not give a precipitation reaction is due to this preventive action of globulin.

The preventive action of unheated globulin differs with the complemental action of a serum. It seems to depend on the physicochemical action of globulin.

Therefore a heated serum should be used in Wassermann and Sachs-Georgi's reactions.

Ten Cases of Delayed Congenital Syphilis.—E. D. Spackman (*Lancet,* July 8, 1922) describes ten cases of delayed congenital syphilis, the age of eight of the patients (soldiers) varying between twenty-one and twenty-three years and two (civilians) being sixteen and seventeen years old respectively. The age incidence of these cases is high and very unusual, as this condition usually becomes manifest at the second dentition or at puberty. In the group of eight patients, there were no signs of a syphilitic breakdown until they engaged in strenuous work at the age of nineteen or over. Four of the group were classed as fit for active service at the front and six of them were actually serving at the front when the syphilitic symptoms appeared.

The author raises two questions: 1. Would these men have manifested the symptoms of congenital syphilis at home without engaging in strenuous work? 2. What was the active factor in the breakdown? A study of the histories of these cases shows: 1. That delayed congenital syphilis is not readily cured. 2. That the neoarsphenamines (novarsenobillon and neokharsivan) speedily clear up the local lesions. 3. That a permanently negative Wassermann reaction cannot be produced by treating these cases. 4. That every congenital syphilitic has a positive Wassermann reaction before treatment and that it remains so throughout life. 5. That there is no age limit at which a relapse cannot occur. 6. That arduous work with mental strain may cause a congenital syphilitic taint to become manifest in an apparently healthy person.

An early and thorough treatment, lasting for two years, should be administered in all cases of congenital syphilis. The persistence of the positive Wassermann reaction is of no great significance, as all of the soldiers led useful lives in spite of the presence of the positive Wassermann reaction since birth; two were married and had healthy children. Patients with obvious congenital syphilis should be given no arduous labor to perform. Delayed congenital syphilis is not a rare occurrence. Aortitis or aneurysms may have a congenital origin and need not be the result of acquired syphilis. All syphilitics should receive competent and thorough treatment. Diseases of the eye, such as interstitial keratitis, iritis, or choroiditis, are important elements in the early diagnosis of syphilis.

Wassermann and Sigma Tests Compared in 569 Cases.—W. T. Collier (*Lancet,* August 5, 1922) found that the sigma test is slightly more reliable and more delicate than the Wassermann reaction; also that it is less complicated. A reading of one to four sigma units only must be regarded as doubtful. If obtained on more than one occasion, it is probably evidence of syphilis. Subsequent tests were also carried out, in which the readings were recorded after seven and after twenty-four hours' incubation. The longer incubation is a great aid in assessing the value of the sigma reading of less than four units (after seven hours' incubation) since a true positive will give a considerably increased degree of flocculation after the longer period. Of 387 cases, thirty-one gave a reading of less than four units; of these twenty-seven, which were all clinically positive or from known treated cases of syphilis, gave such increased flocculation after the longer incubation; four, which were all clinically doubtful, gave no such increased flocculation.

Formalin Test for Syphilis: Some Conditions Controlling Gel Formation.—A. G. Holborrow (*Lancet,* August 5, 1922) found that when serum forms a gel with formalin, it is due to the direct action of the reagent upon serum albumin or serum globulin, or both, and not to any action upon the toxins of the Spirochæta pallida direct. It is probable that the acid protein produces a gel with formalin and that alkali protein does not. The formation of a gel in this case is an indication of decreased alkalinity of the serum, but it does not determine the cause of the decreased alkalinity. The author, therefore, considers the evidence as sufficiently adverse to regard the formalin test for syphilis with reserve.

ENDOCRINOLOGY.

Blood Supply of Thyroid. — E. V. Mastin (*Surgery, Gynecology, and Obstetrics,* January, 1923) states that: 1. The thyroid has a very rich arterial and venous blood supply. 2. There is an extensive anastomosis not only between vessels of the same lobe, but also with those of the opposite lobe. 3. In the event of ligation of all four thyroid vessels the circulation can be reestablished through extraglandular anastomosis. 4. The secretory activity of the thyroid gland is under nerve control. 5. After ligation of the superior thyroid artery a polar ligation should be made in order to cut off the veins, lymphatics, and remaining nerve filaments. 6. Control of hemorrhage is best accomplished by interrupted mattress sutures placed through the remaining gland tissue, by ligation of all bleeding points, and by the use of gauze packing in the wound. 7. Bleeding veins can often be demonstrated by having the patient strain or cough before the wound is closed.

Treatment and Prophylaxis of Endemic Goitre.—Wagner-Jauregg (*Wiener klinische Wochenschrift,* April 20, 1922) asserts that the use of cooking salt containing two mgm. of an iodine salt (potassium or sodium iodide) to the kilogram serves to prevent the occurrence of endemic goitre. This form of treatment has the advantage of acting on the whole population in goitre districts, beginning at the moment of reproduction (intrauterine effect) and also of acting continuously throughout life, independently of individual endeavor.

Pubertas Precox.—John L. Tierney (*The Medical Clinics of North America,* July, 1922) states that precocious puberty or macrogenitosomia precox has been attributed to disturbed function of various endocrines, notably the gonads, adrenal cortex and pineal gland. The most common etiological factor is hypergonadism, with the involvement of the adrenal cortex and the pineal gland next in frequency. In the male, the sexual precocity may be produced by neoplasm and hyperplasia of the testes, suprarenal cortex and pineal gland; in the female, mostly by hyperovarianism, rarely the pineal. Probably most of the cases of masculinity rather than true feminine precocity are cases of hypertrichosis, male countenance, mustache, beard, hypertrophied clitoris, etc., without true secondary sex characters or precocious menses. In cases of hypersecretion, surgery is indicated for tumors; in hyperplasia or hyperactivity, properly directed radiation or suitable endocrine therapy are indicated.

Relation of the Thyroid Gland to the Female Pelvic Organs.—C. M. Wilson and Aleck W. Bourne (*Lancet,* May 27, 1922) present the following conclusions: 1. The basal metabolic rate in most pregnant women, but not in all, is raised above that normally found in nonpregnant women. 2. This basal metabolic rate of different pregnant women varies considerably, but no relationship between these variations in the rate and the clinical condition of the mother is traceable. 3. In the majority of patients, the rise of the basal metabolic rate disappears after delivery, but in a certain number of cases this does not happen, but persists abnormally. The excessive thyroid secretion may produce menorrhagia without pelvic signs. 4, A high basal metabolic rate is also associated with certain forms of menorrhagia, with absence of demonstrable pelvic abnormality. These cases are resistant to all ordinary medicinal and operative measures, but respond readily to exposure of the thyroid gland to x rays. 5. The disappearance of pelvic symptoms is coincident with a fall to the normal basal metabolic rate. Large doses of x rays are not necessary. In a series of cases the patients were treated with initial doses of ½ B or 5 X to each lobe of the thyroid once a week for three doses, the filter being one mm. of aluminum and four layers of wash leather. After that, doses of ⅘ B were given once in three weeks through a filter of 3.5 mm. aluminum and wash leather as before. The rays should not be hard, with a reading not less than 9 on the Bauer qualimeter. The tube used was a Coolidge medium focus, the average doses being seven to eight. Erythema of the skin must be avoided. To avoid the development of myxedema, it is advisable to test the basal metabolism again after six exposures. In some cases more than eight exposures are required, but the necessity for such increased treatment must be determined from time to time by the basal metabolism.

Further Studies Respecting the Pathological and Clinical Significance of Diffuse Adenomatosis of the Thyroid Gland.—E. Goetsch (*Endocrinology,* January, 1922) gives in greater detail the symptoms and pathology of the condition already described by him as diffuse adenomatosis. The patients are mostly women between twenty and thirty complaining of asthenia, fatigability, loss of weight and strength, nervousness of varying degrees, labile pulse with mild tachycardia, tremor, perspiration, vasomotor instability, mental depression and worry, and often a slight elevation of temperature. They do not present the cardinal signs of adenoma and exophthalmic goitre. Nothing peculiar is noted about the eyes. The thyroid gland is often slightly or moderately enlarged, but when palpated is fairly firm, elastic, and shows no nodules, having, however, a granular or lobulated feel. There is an increased vascularity on section and the cut surface bleeds profusely. The gland contains a diminished amount of colloid, thus distinguishing it from the thyroid of simple colloid goitre. Quite the opposite from the condition in colloid goitre, puberty hyperplasia, and exophthalmic goitre, microscopic examination shows the striking and characteristic change to be a marked increase of interstitial cells, with associated atrophy and almost complete disappearance of colloid acini. These interstitial cells, Goetsch believes, produce a secretion which causes the colloid acini to atrophy, and this fact, taken with the abundance of mitochondria found, leads him to consider diffuse adenomatosis a milder form of thyroid adenoma. Treatment consists of resection of approximately three fourths of each thyroid lobe, and considerable success has been attained in a small series of cases.

Existing Views of Thymic Function.—E. Bonilla (*La Medicina Ibera,* February 25, 1922) begins with a description of the histology of the thymus as at present known, then enters into a brief but excellent summary of the views of a great number of recent investigators as to the function of the thymus. The enumeration fully justifies his concluding paragraph: "As may be seen from this review, we know nothing certain about the physiology of the thymus, nor whether it ought to be included or not among the glands of internal secretion, for modern investigations do not seem to demonstrate the absence of an endocrine function with any such degree of definiteness as American authors do."

Adrenal Enlargement in Rabbits.—T. L. Squier and G. P. Grabfield (*Endocrinology,* January, 1922) in an effort to determine the mechanism by which thyroid feeding causes an enlargement of the adrenal glands, fed desiccated thyroid extract by the method of intubation to rabbits, to rabbits whose splanchnic nerve had been severed, to rabbits severely and to those mildly traumatized. The results attained are summarized in the statement that trauma or stimulation will produce an adrenal enlargement of apparently the same kind as that resulting from thyroid feeding, but that the same trauma or stimulation plus thyroid will produce still greater enlargement. The enlargement in all cases was largely, if not entirely, cortical.

NEW YORK, WEDNESDAY, JUNE 20, 1923

SURGERY.

The Radical Cure of Hemorrhoids: Modified Whitehead Operation.—John O'Connor (*British Medical Journal,* May 13, 1922) describes his modification and technic:

1. Limit primary dilatation to the insertion of the right index finger in search of polyps, ulcer, etc.
2. Apply pressure forceps at the junction of the skin and mucosa to each of the four cardinal points of the anal circle.
3. With adjoining forceps held in opposing traction, make a rapid incision with a straight blunt pointed scissors until the skin is completely detached.
4. Apply another pressure forceps to the cut edge of the latter between each of the four forceps originally placed.
5. Grasp the eight forceps in the palm of the left hand, insert the left index finger into the rectum and cut lightly around with scissors until the external sphincter appears well in view.
6. The cutting must be done below and external to it until the Whitehead adit (submucosa) is exposed.
7. With the maneuvre mentioned in paragraph 5 continue cutting the attachments to the muscular coat until the hemorrhoidal cylinder can be peeled out by a blunt dissector.
8. Make a vertical slit in the protruded cuff up to the level of the "supra-Morgagnitic" circle; commence a continuous Triollet catgut suture at the apex of the slit, drawing the "red" mucosa into accurate apposition with the skin; then cut transversely, a half inch at a time, at that level and carry on the continuous suture; all spurting vessels should be immediately ligated.
9. Introduce a morphine suppository and a slender roll of dry gauze into the rectum, apply a dry gauze dressing and change daily.
10. On the fifth morning give the patient one ounce of castor oil, sponge the parts after each stool with warm permanganate solution, add a warm permanganate sitz bath, and reapply dry dressing.
11. On the seventh morning the nurse inserts the right index finger annointed with zinc and boracic ointment into the canal to educate the patient to do the same for two months. Any remaining tags are snipped off under eucaine on the ninth day.

Anesthesia in Pelvic Surgery.—W. R. Meeker (*Surgery, Gynecology, and Obstetrics,* December, 1922) states that the efficiency of nerve block anesthesia can be determined only in the absence of deep preliminary narcosis, terminal infiltration, and inhalation anesthesia. Transsacral nerve block with a low epidural injection gives absolute anesthesia of the pelvic floor and viscera in practically all cases. The technic requires practice and patience for mastery, but may be rapidly improved by experiment on the human cadaver and skeleton. The difficulty of execution of nerve block and the delay in the appearance of anesthesia may be obviated by having the anesthesia induced in a separate room especially equipped for the purpose and the injections performed by one skilled in this branch of work. The amount and strength of the anesthetic solution employed should be in proportion to the general condition of the patient and the probable size of the sacral foramina and nerve trunks. In addition to its high degree of safety to the patient, transsacral anesthesia creates as favorble an operative condition for the surgeon as general narcosis. The trouble and consequent loss of the surgeon's time during operation when local infiltration is employed is thus avoided. Many operations have been performed under this method which would have been impossible with peripheral infiltration or the field block methods.

Anesthetics in Common Operations.—Dudley W. Buxton (*Practitioner,* January, 1923) gives several good suggestions. He assumes that in most cases ether will be employed by the drop method from start to finish, following nitrous oxide gas, or after some other preliminary anesthetic. A hypodermic injection of one one hundredth grain of atropine an hour before the anesthetic is given obviates excessive secretion from the glands of the respiratory tract and should be given to all except very young children. Frequently it is wise to associate with the atropine one sixth grain of morphine and one one hundredth grain of scopolamine, but the latter should not be given for brief operations and should not be given unless the patient can be watched by a nurse. After morphine or scopolamine has been administered the patient should be kept absolutely quiet in a darkened room, without talking or moving, and carried to the operating table, otherwise he is likely to be roused and become faint. Flooding the eyes with castor oil as soon as the patient is sufficiently under the anesthetic not to notice, and then covering them, will prevent conjunctivitis from the ether vapor. Overdoses are productive of exhaustion of the respiratory and circulatory systems, severe vomiting, persistent nausea, hiccough, headache, and other bad effects, but seldom produce observable symptoms during the inhalations. Pulmonary aftereffects follow. In fractures and dislocations there is a common but inaccurate belief that chloroform produces greater muscular relaxation than ether; the former does relax muscles more rapidly, but the latter ultimately produces a more complete muscular flaccidity.

Decide For Yourself!

You know whether a remedy is effective or not! You know what you want it to accomplish, and, knowing your patient, you better than anyone else can tell whether it succeeds or fails.

It is on this basis—and this basis alone—that we ask your consideration for

Gray's Glycerine Tonic Comp.

If it does what you want it to do as a systemic tonic in overcoming functional weakness and bodily depression, and does it more promptly, uniformly and satisfactorily in case after case, than any other remedy, you will naturally continue to use it. If it fails, you certainly will not.

Could we take a fairer position in asking you to give Gray's Glycerine Tonic Comp. a reasonable trial in some difficult case needing tonic treatment?

Could we show greater confidence in its therapeutic efficiency?

The Purdue Frederick Co.

135 Christopher Street, New York

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **Depressing Prostration** following **Influenza,** and in the **General Debility** of **Phthisis, Valentine's Meat-Juice** is recommended by many practitioners throughout the world as invaluable in their treatment.

Influenza *and* Phthisis.

Dr. Boulland, *Paris, France:* "In an attack of La Grippe accompanied by complete lassitude, I used VALENTINE'S MEAT-JUICE. With this preparation I established an excellent appetite and restored my strength very rapidly."

E. H. Walker, *Resident Medical Officer Boro Isolation Hospital and Boro Tuberculosis Sanatorium, Derby, England:* "I have pleasure in stating that I have found VALENTINE'S MEAT-JUICE valuable in the treatment of soldiers discharged from the Army suffering from Pulmonary Tuberculosis."

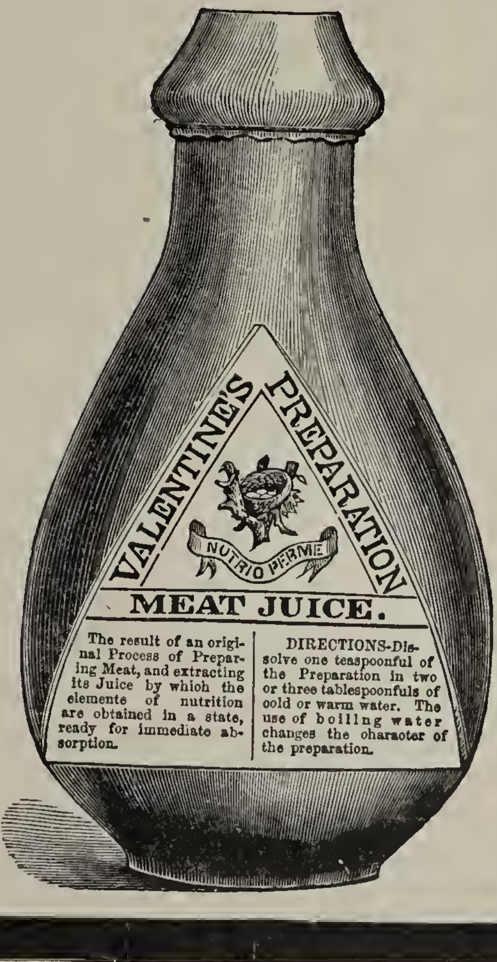
Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,

Richmond, Virginia, U. S. A.

S 160



VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Collectanea.

Diagnosis of Pulmonary Tuberculosis.—Louis Hamman (*Southern Medical Journal,* July, 1922) says that the results of treatment in this disease vary directly with the earliness of the diagnosis. Unfortunately, the natural progress of the infection makes it impossible for the physician to detect all cases at an early stage, for many pass at a stroke from health to an advanced stage. In those which begin more gradually, accurate diagnosis requires all the means of investigation that can be summoned. Not the history alone, nor the physical examination alone, nor the x ray alone, nor the sputum alone, nor tuberculin alone, can solve the problem. He who uses one of these methods to the exclusion of the others is sure to come to grief. Indeed, with all of them at hand, final judgment is frequently difficult and sometimes impossible. The great obstacle is the prevalence of tuberculous infection. We have no way to distinguish in the large group of infected those about to develop manifest tuberculous disease. We must look to the future in the hope that we may learn something of the concatenation of circumstances that lights a latent focus into active disease.

Guaiacol in the Treatment of Tuberculosis.—M. Gustave Dirner, (*Gyógyászat,* 61:334), Budapest, July 10, 1921. Instead of using the common guaiacol preparations, which irritate the stomach lining, dissolving with difficulty and passing into the intestinal canal unchanged, Dirner tried a new hemoglobin guaiacol preparation, which is sold under the trade name of Guaiaglobin. Tablets containing 0.05 gm. guaiacol and 0.20 hemoglobin are well tolerated by the stomach, encourage the production of secretion, improve the appetite and counteract night sweats. The hemoglobin constituents may serve as blood producing agents. In reported cases of early pulmonary tuberculosis, the preparation never failed to improve the prevailing condition.

A New Symptom in Diseases of the Lung and Pleura.—E. Fröschels and F. G. Stockert (*Wiener klinische Wochenschrift,* June 1, 1922) systematically investigated the finding that in cases of pneumonia, a pronounced vowel is heard by the auscultating ear over the affected region as an entirely different vowel, as, for example, the vowels *a, o, u* may sound like the vowel *e.* The observer invariably hears another vowel than the one pronounced. This phenomenon depends upon the intensity of the phonation in such a way that, with an increase in the intensity, the sound became indistinct or disappeared entirely; it occurs only over pneumatic foci and their surroundings, but never over normal tissues. However, over exudative pleurisy and over thickened pleura the changed vowel sounds were not heard. A series of ten pneumonia cases examined, all showed different vowel sounds than the ones pronounced. Frequently, these changed vowel sounds varied within a few minutes or disappeared entirely.

This phenomenon is explainable by the assumption that one vowel is changed to another, when semitones are either added or taken away as a result of the action of the bronchi as resonators—some increase the vocal cord tones and others produce harmonic semitones. As a result of the pneumonic process, some of the resonators are occluded, thereby preventing the access of certain semitones; it is also possible that new semitones may arise in the foci described.

This explanation is further complicated by the fact that interference phenomena may occur in the chest, when semitones are transmitted by way of the thorax and the healthy portions of the lung, and others by way of the diseased portion. This also accounts for the vowel changes in pleuritides, in which case, the compression of portions of the lung might play a similar part.

Biologic Activators.—K. Kottmann (*Schweizerische Medizinische Wochenschrift,* July 13, 1922) with the aid of his photoserologic method, was enabled to show that the reaction depending upon the distribution of the serum colloids is retarded by the addition of normal and carcinomatous organs. In his subsequent investigations, he found that a number of typical vitamin donors (extract of beetroot, wine, codliver oil, etc.) also produce a retardation. This effect depends upon the presence of active substances having the nature of activators—endogenic organic vitamins in normal and carcinomatous organs and exogenic activators in the added extracts. The organism also contains antivitamins, which act as moderators with the aid of which there results a balance under physiological conditions; this results in a regulation of the various nutritional and growth processes. When these processes are disturbed, specific disease pictures appear. In carcinoma there results an abundance of growth activators, thus producing the neoplasm.

Eclampsia in the Late Puerperium.—Bianca Bienenfeld (*Zentralblatt für Gynäkologie,* June 24, 1922) reports a case in which a woman (para-II) developed a puerperal septic endometritis in the early days of the puerperium following an operative interference for the purpose of terminating a normal pregnancy. She was treated with intravenous injections of electrargol which successfully terminated the puerperal process; six days after the appearance of the septic phenomena an eclampsia with a subsequent psychosis developed on the twelfth day of the puerperium. A venesection was followed by recovery.

In making a differential diagnosis it was possible to exclude epilepsy (by the history and the development and recession of albuminuria), hysteroepilepsy, intoxication and organic cerebral disease (by the rapid recovery). In spite of the absence of the usual symptoms associated with uremia, the author considered this case to be one of uremia following acute diffuse glomerulonephritis—a condition rarely described in the literature. The injection of electrargol can be eliminated as an etiological factor in the eclampsia. Owing to the absence of lactation and a possible injury of the liver and intestine by the febrile process, the author also thought of a disturbance (with an existing predisposition to eclampsia) of the lipoid metabolism, in which the threshold limits are overstepped, with the resulting development of convulsions.

Constipation in Young Girls and Women—

especially those who spend much time indoors engaged in sedentary pursuits—is almost invariably attended by a retention of waste and toxic substances. Sooner or later these make their way from the bowel into the general system and give rise to a host of autotoxic ills.

Correction of this condition is imperative, and the safest, simplest and most effective remedy for the purpose is

INTEROL

Directions:

To relieve the constipation of young girls and women, give two to four teaspoonfuls of INTEROL morning and night, increasing or decreasing the quantity as conditions require. As the bowels yield to the action of INTEROL, gradually cut down the dose to the least amount that—taken at bedtime — will assure a daily evacuation.

a pure mineral oil of the proper density and viscosity to assure satisfactory lubrication of the intestinal canal, and thus relieve and correct bowel inactivity without the usual disagreeable effects of cathartics as commonly employed.

Besides lubricating the canal, INTEROL renders the feces soft and plastic, thereby promoting their easy passage and evacuation with gratifying freedom from discomfort and distress.

It would indeed be difficult to suggest any more serviceable and agreeable medium for the correction of constipation, with its attending autotoxemic conditions, than INTEROL.

Sample and Interol brochure on request.

The Clinical Aspect of Postoperative Eclampsia.—H. Thaler (*Zentralblatt für Gynäkologie,* June 24, 1922) reports a case of eclampsia occurring during the latter part of the puerperium. A fever developed on the fifth day of the puerperium and gradually rose until the patient became comatose on the ninth day postpartum, when two typical eclamptic attacks occurred at three hour intervals. The patient's general condition improved during the next two days, when there was another rise of temperature with clouding of the sensorium, paralytic and sensory disturbances of the extremities, right facial paralysis and strabismus, which were followed by death on the twelfth day postpartum. The necropsy revealed cerebral changes in the form of a total thrombosis of the greater falciform sinus and of both transverse sinuses and circumscribed hemorrhages and softenings in the medullary layer of both frontal lobes; also croupous endometritis of the placental site and embolism of the right pulmonary artery and thrombosis in the region of the pelvic veins. On reviewing a series of 472 cases of eclampsia, including eighty-one postpartum cases, only three similar cases were found, occurring eighteen, twenty-two, and thirty-nine hours postpartum. Those cases occurring a short time postpartum seem to be more favorable prognostically than those occurring later. The latter are characterized particularly by the occurrence of severe posteclamptic psychoses and more frequent epileptic attacks. Most of the posteclamptic psychoses occurring in cases characterized by the severity of their course and high mortality were those occurring later than three hours postpartum and those pastpartum eclampsias occurring during the first three hours postpartum were characterized by a very mild course and low mortality. Excellent results in the treatment were achieved with venesection, although chloral hydrate, morphine and the Stroganoff treatment were also given.

Eclampsia: Evolution as a Causative Factor.—S. E. Kark (*British Medical Journal,* June 10, 1922) bases his theory on the following facts: 1. All the changes occurring in pregnancy are functional. 2. All pregnancies are not quite normal, as evidenced by the functionless changes. 3. Owing to the tardiness in evolution of the placental form of reproduction, pregnancy approaches, in some degree, primitive conditions, as evidenced by the secondary feminine characteristics of the pregnant woman being less marked and the approach to the masculine type in many respects, such as the overgrowth of hair, coarsening of the features, thickening of the skin, hypertrophy of the bones, enlargement of the hands and feet and stability of calcium metabolism. Another result of this physiological atavism of pregnancy is the survival of the state of hyperpituitarism in pregnancy. This is shown by the fact that the physiological requirements for gestation are stimulated by the hormone from the anterior lobe of the pituitary and the pathological changes are due to its overactivity. In the later stages of pregnancy, the hormone of the posterior lobe stimulates the physiological requirements and the pathological changes are due to the hyperactivity of the posterior lobe plus the morbid changes due to the anterior lobe hormone. The prodromal symptoms of eclampsia are due solely to the overactivity of the anterior lobe, the pre-eclamptic symptoms are due to the overactivity of both the anterior and posterior lobes, while the eclamptic symptoms are due to oversecretion of the posterior lobe only.

The symptoms (prodromal) due to the anterior lobe are practically the same as in acromegaly, namely nervous irritability and unbalance, vomiting and epigastric pains, headaches, somnolence and cramps and twitchings of muscles. The preeclamptic symptoms are due to hypertrophy of both parts of the gland. The anterior lobe produces objective symptoms of pressure on the neighboring centres and nerves, as on the optic nerve and chiasm, producing symptoms of disturbed vision. The preeclamptic symptoms from overactivity of the posterior lobe are increased blood pressure and urinary changes, such as oliguria, high specific gravity, albuminuria, blood and hyaline, epithelial and granular casts; the eclamptic symptoms are tonic and clonic convulsions from contractions and spasms of the cerebral bloodvessels from the pressor action. The pathological anatomical findings corroborate these clinical symptoms by showing evidence of irritation in the posterior lobe of the pituitary, the brain, liver, and the kidneys. Eclampsia is therefore not due to any accidental external agent, nor is it the result of a morbid derangement producing poisons or toxins from either the fetus, uterus, or the intestine, but it is essentially a physiological process overdone—an excess rather than a perversion of an essential product. This is due to the comparatively short evolutionary experience of nature with the placental form of reproduction.

Chorionepithelioma.—Herbert A. Black (*Colorado Medicine,* June, 1922) maintains that the frequency of this disease should warn every physician to be on the alert in cases of persistent bleeding after the termination of pregnancy, especially if it is of the pathological type, for the heavy mortality incident to this form of tumor, though rare, makes it highly desirable that the diagnosis be made at an early stage. In no other class of malignant cases is there so apt to be a mistake in diagnosis at the onset of the symptoms, which results in delay until the disease has made such progress as greatly to increase the mortality and render operative measures all but useless. Clinical symptoms may be sufficiently diagnostic to justify operation in the absence of laboratory findings. Abdominal hysterectomy is the operation of choice, and this is not contraindicated by metastases.

Treatment of Asylum Dysentery by Means of Antidysentery Serum.—P. Lornie and D. Ellis Jones (*British Medical Journal,* June 17, 1922) report unprecedented results in the treatment of dysentery in institutions with serum prepared by injecting horses with cultures of Shiga, Flexner's and Kruse's bacilli. The amounts of the serum used varied between twenty and forty-five c. c. (usually twenty-five c. c.) which were injected subcutaneously in the ten cases reported. Apart from the rapid clearing up of the blood and mucus and the cessation of the diarrhea, the rapid fall in the temperature and the immediate and marked physical improvement were striking features.

Decide For Yourself!

You know whether a remedy is effective or not! You know what you want it to accomplish, and, knowing your patient, you better than anyone else can tell whether it succeeds or fails.

It is on this basis—and this basis alone—that we ask your consideration for

Gray's Glycerine Tonic Comp.

If it does what you want it to do as a systemic tonic in overcoming functional weakness and bodily depression, and does it more promptly, uniformly and satisfactorily in case after case, than any other remedy, you will naturally continue to use it. If it fails, you certainly will not.

Could we take a fairer position in asking you to give Gray's Glycerine Tonic Comp. a reasonable trial in some difficult case needing tonic treatment?

Could we show greater confidence in its therapeutic efficiency?

The Purdue Frederick Co.
135 Christopher Street, New York

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In low forms of **Pneumonia** and **Exhaustion,** in the **General Debility** and **Depressing Prostration** following **Influenza** it is recommended by many practitioners throughout the world as invaluable in their treatment.

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Pneumonia *and* Influenza.

William H. Peters, M. D., *Admitting Physician, Camp for Consumptives, State of Rhode Island, Providence, R. I.:* "VALENTINE'S MEAT-JUICE was the only nourishment retained by my five-year old daughter during an attack of Pneumonia. I consider that it saved her life and believe it to be the best product of its kind."

Cavalier Dr. Enrico Ballerini, *Late Surgeon to the Hospital of Rome, Italy:* "I have used VALENTINE'S MEAT-JUICE in the treatment of patients, and also personally, after having been very ill with Influenza, and I must say it is an excellent tonic in conditions of great organic weakness. It is also very agreeable. I have prescribed it with the greatest satisfaction for convalescents and invalids restricted to a liquid diet."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,
Richmond, Virginia, U. S. A.

S 172

Medical College Founded at Jerusalem.—The Jewish Physicians' Committee of the World Zionist Organization, acting in cooperation with the Palestine Foundation Fund, and consisting of Dr. Nathan Ratnoff, chairman, with Dr. David Kaliski and Dr. Samuel J. Kopetsky, have recently returned from Palestine, after several weeks' stay, where a site of about thirty acres on the Mount of Olives was acquired for the establishment of the Medical College of the Hebrew University at Jerusalem. Some $300,000 have already been subscribed by physicians of the United States for the establishment of the school. A building has been rented as temporary quarters for a school for research in tropical diseases and plans have been completed for permanent buildings, on which actual work will be begun as soon as the rainy season is over. Dr. Ratnoff reports the absolute need of research work in the endemic diseases and in scientific sanitation as most urgent. Instruction in medical studies will be entirely in the Hebrew language which will enable native students to continue to matriculation in a medical college at home, where, heretofore, for lack of such facilities, they have been compelled to go abroad for this purpose. The Medical College will be directed by a Board of Governors, one half of the members of the Board to be appointed by the Physicians' Committee, the other half by the World Zionist Organization. Included on the Board of Governors are the following American physicians: Dr. S. S. Goldwater, Dr. Israel Strauss, and Dr. Leon Louria. Representatives of the World Zionist Organization are Dr. Chaim Weizmann, Prof. Otto Warburg, Dr. R. Solomon, and Dr. M. D. Eder.

Rockefeller Institute Extension.—Announcement was made a few days ago of the purchase by the Rockefeller interests of another whole city block, from Sixty-third to Sixty-fourth Street and fronting on the East River, for future enlargement of the Rockefeller Institute for Medical Research. The first purchase of the property, which now embraces five entire blocks on the East River, was made by John D. Rockefeller in 1903, when he acquired the three blocks bounded by Sixty-fourth and Sixty-seventh Streets, Avenue A and the river, part of the original William C. Schermerhorn farm. No streets were cut through east of the river at the time of this purchase. The first street to be opened was Sixty-seventh, the block between Sixty-seventh and Sixty-eighth, Avenue A and the river being intended as a site for the Presbyterian Hospital. When the more ambitious plans of association of the Presbyterian Hospital with the College of Physicians and Surgeons of Columbia University was adopted, this site was abandoned and a location in Washington Heights acquired, leaving the former for future development of the Medical Institute for Research. The entire property with its hospital, laboratories and other buildings is valued at about two million dollars for assessment purposes, though about half of it—that part occupied by the medical buildings—is exempt from taxation. The cornerstone of the first structure was laid in December, 1904, by Dr. Simon Flexner, then, and continuously since that date, chairman of the Board of Governors. The attention of the medical world will naturally be directed to the future development and expansion of the activities of the institute by reason of the fact that the interests controlling these activities are willing to provide every facility for placing the Rockefeller Institute in the foremost place among the world's greatest medical research organizations.

Child Welfare Organizations Unite.—The two national organizations engaged in promoting the health of the chlidren of this country have voted to unite under the title of American Child Health Association. The two organizations as heretofore known, are the American Child Hygiene Association and the Child Health Organization of America; both have been devoted primarily to promoting the health of children. For thirteen years, beginning with the formation of the American Association for the Prevention of Infant Mortality, there has been a group of physicians, nurses, and others interested in child health, who have built up throughout the country organized groups of workers to carry out measures known to be sound in the preservation of the health of mothers and of babies in the matter of child hygiene work. The membership has grown from an original of 917 to its present membership of 2,047, and in the number of State Bureaus of Child Hygiene from twenty-nine to forty-seven.

An Interesting Hospital Site.—The Bronx Hospital has just purchased land for the construction of a new main building which has an interesting history. It was sold by Indians in 1648 to Col. Robert Morris, whose heirs held it until 1848; there was then one conveyance to James Herold, from whom the John Eichler Brewing Company bought it something over fifty years ago. It has never changed hands since. With this addition to their holdings the Bronx Hospital has a total frontage on Fulton Avenue of 211 feet and an increase of its present holdings of 151 feet on 169th Street. The old buildings will be used for a maternity hospital, nurses' training school, and dormitories.

French Doctors Visit America.—A delegation of members of the faculty of the medical school of the University of Strasbourg, Alsace, have come to the United States as the guests of the Rockefeller Foundation for the purpose of studying the organization and methods of American medical schools. The visiting commission is made up of the dean, Dr. Georges Weiss, professor of biophysics, and six other influential members of the faculty, representing both laboratory and clinical branches—Dr. Léon Blum, professor of clinical medicine, Dr. Paul Bouin, professor of histology, Dr. Camille Duverger, professor of ophthalmology, Dr. P. Masson, professor of pathological anatomy, Dr. Maurice Nicloux, professor of physiological chemistry, and Dr. Lucien Pautrier, professor of dermatology and head of cutaneous diseases clinic. After a brief stay in New York members of the commission, following their special interests, will visit a few of the leading institutions for medical teaching and research in the United States, among them the Rockefeller Institute for Medical Research; the College of Physicians and Surgeons, Columbia University; the Cornell Medical School; the Johns Hopkins Medical School; the Harvard Medical School; the medical schools of the University of Pennsylvania, the University of Michigan, the Washington University, St. Louis; and the hospitals affiliated with these institutions.

Valentine's Meat-Juice

In **Hospital** and **Private Practice** and **in their own persons** when ill, **Physicians** have demonstrated the **Power** of **Valentine's Meat-Juice** to **Sustain** and **Strengthen** the **Weakened Vital Forces** when the **Digestive Organs** are **Impaired**

Debility, Exhaustion *and* Anaemia.

Dr. Julian Calleja, *Pres. Royal Academy of Medicine of Madrid, Spain:* "It is with the greatest satisfaction I inform you that I consider VALENTINE'S PREPARATION OF MEAT-JUICE to be of a very superior order for invigorating the nervous system, for which I use it myself and prescribe it to my patients."

John Tanner, M. D., LL. D., *Senior Physician Farringdon General Dispensary for Diseases of Women and Children, London, England:* "In cases of Flooding or Hemorrhage of any kind, Fevers, low forms of Pneumonia, Extreme Exhaustion when the stomach is too irritable to retain any ordinary preparation, then VALENTINE'S MEAT-JUICE will be found to be a perfect God-send. I cannot speak too highly of it, as I have found it of such immense advantage to me in the treatment of the most anxious and serious cases under my care."

Physicians are invited to send for brochures containing clinical reports.

Miscellany.

Ten Years of Intravenous Therapy in General Practice.—John Howard Frick (*Medical Review of Reviews,* July, 1922) cured a case of advanced, virulent and generalized streptococcus infection, in which all other methods of treatment failed, with thirty intravenous injections of one gram of sodium salicylate in twenty c. c. of sterile distilled water, given every eight hours. In all types of pneumonia, pleurisy with or without effusion, and generalized infectious, socalled rheumatism, either muscular or articular, he obtained excellent results with the intravenous injections of one to two grams of sodium salicylate dissolved in twenty c. c. of sterile water, given every eight to twelve hours. Ten cases of anemia were treated with sodium salicylate, one half to one gram in ten c. c. of water, injected intravenously every third or fourth day. It increases the hemoglobin and red blood cell count. Another series of ten cases were treated with iron and arsenic. In sixteen cases of severe and persistent chronic arthritis, responses were obtained from the injection of two grams of sodium iodide in twenty c. c. of sterile water, given at five or seven day intervals or until signs of iodism appear. In acute cases this dose was given every eight to twelve hours. This treatment is also effective in Berger's disease, indolent ulcers, asthma, chronic headache and in diseases with connective tissue proliferation in the bloodvessels, viscera, or in and about joints. Urotropin, one half to one gram dissolved in ten c. c. of water, given either alone or in combination with one gram of sodium salicylate (requiring twenty c. c. of water) is effective in pyelitis, otitis media, mastoiditis, pneumonia, and in pleurisy with effusion. In endarteritis obliterans, not too far advanced, a two per cent. solution of sodium citrate in eight ounces volume, given intravenously every third or fourth day, is practically a specific.

Echinococcus Anaphylaxis. — Johann Hugo Botteri (*Wiener klinische Wochenschrift,* May 25, 1922) asserts that hydatid fluid should be considered as a true antigen because with it both active and passive anaphylaxis may be produced and also because with a characteristic shock the hypersensitive organism may be desensitized. Man can be easily sensitized with a single subcutaneous injection of two to five c. c. of the antigen and sometimes even by repeated intracutaneous inoculations of 0.1 c. c. of the antigen, but with the intravenous route it is difficult and can be accomplished only with large doses; with oral administration, enormous doses are required. The hypersensitiveness was tested with intracutaneous inoculations of 0.1 to 0.2 c. c. of sterile hydatid fluid. After eight to ten days, the intracutaneous reaction becomes positive in the form of an erythema and infiltration of the skin as large as a five crown piece.

The antigen keeps for months if hermetically sealed and mixed with two per cent. chloroform. The intracutaneous reaction in patients with echinococcus disease is striking with the use of 0.1 to 0.2 c. c. echinococcus cyst contents injected in the form of a wheal. On the day after the injection there may be an erythema the size of the palm of the hand and swelling of the skin, usually associated with a marked subcutaneous inflammatory edema, which may be extensive. The edema increases for forty-eight hours and usually recedes completely on the fourth day. Only a skin infiltration of at least five to six cm. diameter, especially when associated with a simultaneous subcutaneous edema, is recognized as a positive reaction. A temporary edema occurs chiefly when the echinococcus cyst is suppurating, but the reaction returns as soon as the patient recovers from the operation.

With this test very small cysts can be diagnosed. The duration of the hypersensitiveness may be many years, even though the patient is clinically well. The artificial hypersensitiveness lasts about four weeks. It is possible to transmit a passive anaphylaxis to other persons, requiring, however, large doses (one hundred to two hundred gm.). After intravenous antiserum injections, the passive anaphylaxis appears on the next day, but it is soon lost; with subcutaneous injections, the passive hypersensibility appears on the fifth day, but lasts longer. A local passive tissue anaphylaxis could not be developed. Antigen antibody formation, desensitization after long continued intracutaneous reactions and a weakening of the reaction cannot be induced. Larger doses are undesirable because they produce necrosis. For purposes of desensitization, the author used the intravenous route and he carefully injected very small doses in the beginning in order to produce a slight shock in cases of spontaneous and artificial hypersensibility.

In hypersensitive persons, immediately after the injection there is a congestion of the head, reddening of the conjunctiva, occasionally vertigo, and after a few minutes a general urticaria, especially marked at the site of the previous cutaneous reaction; there is also a true recrudescence of the old reaction, including those incited with antigen, both when it does and when it does not contain albumin; there may also be vomiting and tenesmus, slight rises of temperature and traces of albumin and urobilinogen in the urine. Absolute desensitization against the intracutaneous reaction occurs in three to seven days. The urticaria recedes in one to two hours after the shock and the patient is entirely recovered.

The shock may also be produced by antigen which was boiled for a short time, provided the albumin is not precipitated as a result of the alkaline reaction. Antigen not containing albumin (in animals) does not produce the shock. The eosinophilia in echinococcus disease is an anaphylactic symptom.

Two Hundred and Twenty-five Cases of Pneumonia.—Ambrose W. Owen (*British Medical Journal,* June 17, 1922) reports a mortality of 14.2 per cent. in his series of cases of pneumonia. The usual treatment of milk, beef tea, albumen water and plenty of cold water until after the crisis was given. He considers the most useful drug to be ammonium carbonate, giving five grains every four hours to adults and one grain for an infant of one year and proportionally according to age. Patients who were treated with strychnine and digitalis died. These drugs seem to be more useful in cardiac debility following the crisis. Morphine was given only to adults. The hypodermic injection of morphine he believes to be harmful.

Sluggish Bowel Action in Childhood

is usually due to errors in feeding. Subjecting these fundamentals to the customary careful correction,

INTEROL

may be administered coincidentally to relieve the immediate condition.

This pure, tasteless and odorless mineral oil—notably free from the greasiness common to such products—has proved of exceptional value as a safe and dependable means of moving the bowels of young children, and this without the griping, straining and after-constipation by which the use of castor oil and other drastic cathartics is so frequently attended.

The constantly-growing number of physicians who prefer INTEROL to any other media in the routine management of constipation in early life is its own best endorsement.

Dosage in Children

Begin with a half to one teaspoonful, 3 times a day before meals. Increase or decrease dose until one good movement is obtained daily. Then gradually decrease to the point where a small dose at bedtime will maintain this result.

Sample and Interol brochure on request.

GRANDE SOURCE

Tuberculosis of the Eye.—F. Dimmer (*Wiener klinische Wochenschrift,* May 11, 1922) asserts that there is a close relationship between the eye and the disease, tuberculosis. An extensive trial of tuberculin therapy has shown that many tuberculous eye conditions are amenable to it. There is no reason for the objection to it on the parts of both the medical profession and the laity. A more extensive use of tuberculin therapy is urged.

A Case of Antrochoanal Polypus of Exceptional Size.—W. G. Dawson (*Lancet,* June 3, 1922) reports an antrochoanal polyp, weighing 9.5 drams, which had been present for several years. It was a globular glistening, pearl colored, firm growth, filling the entire pharynx and bulging the soft palate forward; its lower limit was seen only with difficulty by strongly depressing the tongue. Respiration and deglutition were impeded remarkably little. There were no symptoms except a peculiar muffled speech and suffocation when the patient turned on his back during sleep.

Hibbs's Operation.—S. Widere (*Norsk Magazin for Laegevidenskaben,* September, 1922) describes the operation and quotes Hibbs's own results from the treatment of spondylitis by this method. The operation is indicated in: 1. Tuberculous spondylitis; 2, pronounced, progressive kyphoscoliosis, obstinate to other treatment; 3, painful, traumatic conditions, in fractures and dislocation, and in 4, spondylolisthesis. Widere has operated in seven cases of tuberculous spondylitis with seemingly good results, also one patient with continuous pain, localized to columna and originating in a trauma. One case of marked kyphoscoliosis, and one of spondylolisthesis are at present under observation, but not yet operated upon. Hibbs's operation is recommended.

Close Relationship of the Erythrogenetic and Leucogenetic Functions of the Bone Marrow in Disease.—Eugene P. Pendergrass and Henry K. Pancoast (*American Journal of the Medical Sciences,* June, 1922) define erythemia as a disease of the erythroblastic tissue of the bone marrow and report a case in which röntgen ray treatment proved efficacious. X rays destroy or inhibit the formation of red cells and are therefore indicated in the treatment of erythemia, and also in the treatment of secondary polycythemia when such cases fail to respond to treatment by drugs and venesection.

Swelling and Distention of the Areola of the Nipple During Pregnancy.—P. Sfameni (*Zentralblatt für Gynäkologie,* May 13, 1922) concludes that the swelling of the areola of the nipple depends upon neither an edematous infiltration nor upon other analogous conditions: this, as well as the greater spreading at the surface, depends upon the hypertrophy of the mammary gland. The diagnostic significance of the swelling of the areola of the nipple and of its increased size is pronounced. The swelling and spreading of the areola at the surface also has a prognostic value, as it is due to an intensive hypertrophic activity of the mammary gland. In fact, the conclusion can be drawn that the function of the mammary gland will be abundant during the period of lactation.

Transmission of Hypersensibility in Human Beings.—A. de Besche (*Norsk Magazin for Laegevidenskaben,* September, 1922) succeeded in producing passively hypersensibility to horse albumen (horse serum) in the skin of quite normal individuals, in three out of fifteen cases, by intracutaneous injection of serum from asthmatic patients, whose asthma was distinctly due to sensibility to horse. This sensibility was only of a local character, however, as other portions of the skin not injected gave no reaction. The same antigen (horse serum) which injected subcutaneously or intravenously into the asthmatic patients would cause a severe general reaction, produces when injected intracutaneously into this isolated hypersensitive local area of the normal individual the sister disease to asthma, i. e., urticaria. These experiments may help to throw more light on what must now be considered as anaphylactic types of asthma.

Bleeding Mammæ and Their Relation to Cancer.—J. K. Hald (*Norsk Magazin for Laegevidenskaben,* August, 1922) concludes that the most frequent cause of this rare condition is new growth of the mammæ. Other causes are disorders of menstruation and an inflammatory condition of the mammæ. Among the benign growths accompanied by this symptom may be mentioned cyst adenoma and intracanalicular papilloma. In the latter bleeding of the mammæ often constitutes the only visible symptom. In cancer, bleeding of the mammæ is reported in one to nine per cent. of the cases, but as malignant cancer is of much more frequent occurrence in the breast, than benign growths, bleeding will always arouse a suspicion of cancer. The only treatment of bleeding mammæ when caused by new growth, whether benign or malignant, should be operative, as benign tumors may undergo malignant degeneration.

Embolism and Thrombosis of Superior Mesenteric.—E. Klein (*Surgery, Gynecology, and Obstetrics,* October, 1921), from a study of cases, concludes that: 1. Occlusion of the mesenteric vessels is most often effected by an embolus or a thrombus. 2. Experimentally, by varied disturbances of the intestinal blood supply, there may be produced lesions varying from limited necrosis of the mucosa to extensive infarction of all the intestinal coats. The milder lesions are not fatal and heal completely. 3. It seems likely that these experimental findings are closely paralleled by the lesions in man. 4. Closure of the superior mesenteric artery in man may be followed by a, complete establishment of a competent collateral circulation which will, 1, persist effectively throughout the patient's life, or, 2, subsequently break down, usually because of aggravated disease of the heart or the bloodvessels; b, intestinal obstruction without infarction owing to a blood supply sufficient for life of the parts but not for function; c, intestinal infarction, with the injury varying through all stages from a moderate lesion of the mucosa to pronounced necrosis of the intestinal walls. 5. Following obstruction of the trunk of the artery the third effect noted above is the most common. 6. Following obstruction of a branch the first effect is the most common. 7. A favorable outcome without operation does not exclude the diagnosis of embolism or thrombosis of the superior mesenteric artery.

THE RADIUM EMANATION CORPORATION
250 West 57th Street
New York, N. Y.

Telephone Circle 3649

The Radium Emanation Corporation announces the opening of its laboratories at 250 West 57th Street, New York, and the inauguration of a service to the medical profession in the commercial distribution of radium emanation.

To the members of the profession specializing in X-ray and radium therapy, Gynecology, Urology, Dermatology and diseases of the Nose and Throat, this service will be of special benefit, as we are prepared to furnish at any given time, as an aid to their therapy, emanation, either in the form of tubes or "seeds" with special applicators for their introduction.

Our laboratories are open for inspection and we welcome you that you may see the facilities we have for rendering this service.

Upon request, we will mail you a brochure containing an resumé on "The Use of Radium Emanation in the Treatment of Disease" especially prepared by William Duane, Ph.D., D.Sc.,
Consulting Physicist to the Radium Emanation Corporation, Research Fellow of the Cancer Commission, Collis P. Huntington Memorial Hospital, Boston, Mass.

J. E. Underwood, M.A.
Resident Physicist

Miscellany.

Pharmacology of Benzyl Compounds.—Carl Nielsen and John A. Higgins (*Journal of Laboratory and Clinical Medicine,* November, 1921) state that all the benzyl esters investigated produced relaxation of intestinal muscles, lowered the blood pressure, and depressed the respiration in a manner corresponding in a general way to the action of benzyl benzoate as demonstrated by Macht. There seems to be a correlation of benzyl hydrolysis and smooth muscle relaxing property in the series of benzyl esters investigated, with the exception of the salicylate and acetyl salicylate, in which the rate of hydrolysis to give benzyl alcohol is not a criterion of pharmacological action. Of the twelve benzyl compounds tested, benzyl acetyl salicylate appears to be the most powerful intestinal relaxant, and benzyl salicylate is also very efficient.

Observations on the Pharmacology of Some Benzyl Esters.—Carl Nielsen and John A. Higgins (*Journal of Laboratory and Clinical Medicine,* April, 1921), using the method described by Jackson, obtained marked intestinal relaxation following injections of relatively small amounts of benzyl benzoate and benzyl cinnamate. The latter produced a greater intestinal relaxation than the former in equal amounts. Benzyl cinnamate lowered the blood pressure less than benzyl benzoate. These results are not in accord with those of Mason and Pieck, who report a negligible effect, or none at all, on the intestine, although the method was somewhat different. Benzyl cinnamate is a solid compound at ordinary temperatures, readily melting at body temperature, and like benzyl benzoate, virtually noxtoxic when administered orally. After repeated injections of large doses of benzyl esters into the blood stream, the authors noted that the arterial blood becomes very venous in appearance, but no difference in the coagulation time of such blood was recorded, as compared with normal arterial blood from the same animal.

The Danger of Epidemics in Europe and What Is Being Done to Prevent Their Spread.—C. Näslund (*Hygeia,* September 15, 1922), after studying the statistics of epidemics in Europe during the war, shows how most of the infectious diseases spread from Russia to the Western European countries, though not to any appreciable extent until after the inner disorganization caused in these countries by the war. In 1919 and 1920 these epidemics reached their maximum. In 1921 there was a considerable decrease in the number of cases reported, except of cholera in Russia. This decrease must be attributed to the preventive measures instituted in some of the countries. Statistics are, however, not reliable regarding smallpox, dysentery and relapsing fever.

From the numerous reports from competent and reliable sources, it is safe to assume that the number of cases greatly exceeds that recorded in the statistics, and that in both Ukrania and Russia they have shown a rapid increase during the past year. In the famine districts, the cause of death is seldom recorded. That the spread of epidemics should become colossal in localities where neither soap, disinfectants, nor medicines are to be had is selfevident. The wholesale migration that is under way from Russia constitutes a great menace to the population of Western Europe. This migration is due partly to the hectic political conditions of Russia and partly to the horrible living conditions in that country. Of all the famine and epidemic centres of Russia, Ukrania doubtless presents the worst.

The sanitary regulations of Russia are ordered by the Public Health Commission, which includes a department for epidemics and also a department for prevention of disease. Local health departments are to be found in the various provinces. A similar organization is in charge of public health in Ukrania. Five conferences have been held by epidemiologists and bacteriologists in an effort to agree upon the best method of fighting the spread of these diseases. A sanitary cordon has been established along the Russian boundaries. The Warsaw convention also advised the quarantine of all vessels from Russia during the cholera months, i. e., June, July, August, and September. In Russia the hospitals are to be repaired, new hospitals erected, disinfecting and delousing stations distributed through the disease districts, and bacteriological laboratories supplied as well as disinfectants and medicines.

Immunological Study of Strains of Bacillus Pfeifferi Isolated from a Case of Meningitis.—Ruth A. Anderson and Oscar T. Schultz (*Journal of Experimental Medicine,* May, 1921) isolated five strains of B. Pfeifferi from a case of meningitis from the spinal fluid, blood, nose, throat and nasopharynx. These strains showed distinct immunological differences, those from the nose and nasopharynx being more closely related than any others, and some slight relation may have existed between the spinal fluid and the nose strains. The pathogenicity of the five strains for rabbits also varied. In spite of the immunological differences the authors believe that the strains are genetically related. The strain variations which have been noted by immunological methods do not support the theory of the etiological relation of this organism to epidemic influenza, unless it can be demonstrated that such variations are due to instability of the organism.

Experiments on the Specific Effect of Bacteriophages.—Oskar Bail and Tai Watanabe (*Wiener klinische Wochenschrift,* April 20, 1922) were able to show that the reproduction of bacteria and bacteriophages proceed independently of each other. This finding is of great importance and shows that the living but vegetatively resting bacillary body is not destroyed but that only the reproductively active part is destroyed. The reproductive process, the function of the bacterial hereditary part, must be inhibited so that the bacteriophagic effect may appear, which for this reason must be considered as autolytic with reserve. In fact the observation of cellular reproduction shows that as a result of the activity of the hereditary substance (chromatin) two kinds of processes are seen in the rest of the cell nucleus: the dissolution of the old nucleus with its covering and the associated development of two new ones. This can be interpreted that the chromatin becoming active has the power of dissolving the vegetative cell nucleus and secondly to cause its redevelopment.

Decide For Yourself!

You know whether a remedy is effective or not! You know what you want it to accomplish, and, knowing your patient, you better than anyone else can tell whether it succeeds or fails.

It is on this basis—and this basis alone—that we ask your consideration for

Gray's Glycerine Tonic Comp.

If it does what you want it to do as a systemic tonic in overcoming functional weakness and bodily depression, and does it more promptly, uniformly and satisfactorily in case after case, than any other remedy, you will naturally continue to use it. If it fails, you certainly will not.

Could we take a fairer position in asking you to give Gray's Glycerine Tonic Comp. a reasonable trial in some difficult case needing tonic treatment? Could we show greater confidence in its therapeutic efficiency?

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **General Debility** with **Impaired Digestion** of **Phthisis,** and in the **Depressing Prostration** following **Influenza** it is recommended by many practitioners throughout the world as invaluable in their treatment.

Phthisis.

J. Mertens, M. D., *A. T. O. Bristol Municipal Tuberculosis Dispensaries, Bristol, England:* "I am pleased to state that the results obtained from VALENTINE'S MEAT-JUICE were very satisfactory indeed in all cases where no other kind of food could be used. It produced excellent results with wounded soldiers suffering from Tuberculosis of the lungs."

Dr. Gouel, *Physician in Chief Villepinte Hospital for Consumption, Paris, France:* "VALENTINE'S MEAT-JUICE succeeds well in cases of Anæmia and in the treatment of Tuberculosis in an advanced stage when the stomach is intolerant."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY,

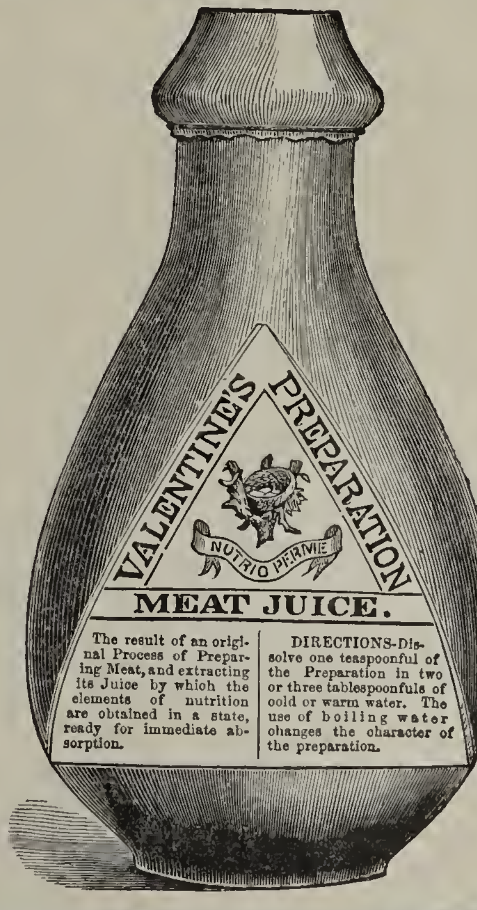
S 151



VALENTINE'S PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Effect of Sodium Germanate upon the Total Hemoglobin of the Albino Rat.—Joseph E. Nowrey, Jr. (*Bulletin of the Johns Hopkins Hospital,* September, 1922) found that in rats injected with seventeen mg. of sodium germanate to the kilo of body weight there was a marked increase in the number of erythrocytes to the c. c. of blood, a moderate increase in the concentration of the hemoglobin, and a variable increase in the blood volume. There was no evidence of a concentration of the blood plasma in any of the animals. Nowrey draws the conclusion from these and previous experiments that the increase in the red cells of the blood of the rat following the injection of sodium germanate is in all probability due to a stimulation of the bone marrow and not an effect which follows a concentration of the plasma.

Night Sweats: Their Significance and Prevention.—Marcus Peterson (*Lancet,* July 29, 1922) suggests that the term night sweats is a misnomer and should be changed to slumber sweats, as the sweating may occur at any time when the patient sleeps. In the early stages of pulmonary tuberculosis and in the absence of any other infection, the sweats are often the only indication of the presence of an active tuberculosis. They do not occur a few weeks before death because the patient's resistance has been overcome. Various drugs have been recommended for slumber sweats, but these are unnecessary, as the sweats can be prevented without drugs, simply by having the patient sleep on a grass mat over the mattress or by sleeping without a mattress on canvas. The sweats are due to the presence of large amounts of bacterial products (toxins) in the blood; the sweats may appear in any bacterial disease and consequently they are not diagnostic of pulmonary tuberculosis, as is generally believed.

The Justification for Advising Birth Control in a Case of Idiopathic Amaurotic Idiocy.—E. Sachs (*Zentralblatt für Gynäkologie,* May 20, 1922) reports a case of Tay-Sachs's familial amaurotic idiocy. The mother sought advice as to the diagnosis and prognosis and also regarding the advisability of having another child. The child seemed normal when born but after six months it no longer showed fixation of the eyes and it became dull and unresponsive; the eyes wandered aimlessly and the head and extremities became gradually weaker. The diagnosis was established by examination of the eye grounds, which showed characteristic sharp limitation of the papilla, with a pronounced white discoloration, especially in the region of the macula; the retina was cloudy, with a light white ring and a cherry red spot (fovea) in its centre. These cases usually end fatally during the second year of life.

This disease frequently occurs without any known cause in several children of a family and almost always in those of Jewish parentage. It is due to an extensive degeneration of the entire central nervous system, with secondary atrophy of the cerebral and spinal nerves. The author asserts that the physician has no right to warn the parents of such children against further pregnancies. He should, however, explain to them that its occurrence may be repeated, but also that it is also possible that healthy children may be born; he must leave further pregnancies as a matter of choice to them.

Giant Centrospheres in Xanthomatous Tumors.—David T. Smith (*Bulletin of the Johns Hopkins Hospital,* September, 1922) studied seventeen xanthomatous tumors with special reference to the presence or absence of giant centrospheres. They were present in nine, or a little over fifty per cent. of the cases, and are probably to be regarded as evidence of degeneration.

Factor Determining the Spread of Red Marrow During Anemia.—Philip D. McMaster and Herbert Haessler (*Journal of Experimental Medicine,* December, 1921) conclude from their study on rabbits that the factor which determines the spread of red marrow during anemia is the presence in the body of hemoglobin, or perhaps of its precursors, in excess of the amount which can be utilized by the marrow already existing.

Effect of Age on Pancreatic Enzymes.—Frederic Fenger and Mary Hull (*Journal of Biological Chemistry,* May, 1921) report that powdered pancreas preparations which have been stored under ordinary conditions for one year deteriorated materially in their diastatic and lipolytic activity, some of the samples having become almost inert. The proteolytic activities of the same samples, however, were unchanged, indicating that trypsin occurring both in the desiccated natural gland and in the activated preparations, is the most stable of the pancreatic enzymes.

The Question of Arsphenamine.—Karl Wagner (*Wiener klinische Wochenschrift,* August 3, 1922) is of the opinion that the dangers of arsphenamine are underestimated and that it is no longer justifiable to refer patients to the neurologist for the purpose of obtaining material for extensive catamnestic experiences. The author sees the chief danger from arsphenamine in the necrotizing effect on the intima of the bloodvessels. He believes that this injurious effect on the bloodvessels, just like arteriosclerosis, may develop insidiously and become apparent only after decades.

Experiences with the Hecht Reaction.—Heinrich Kogerer (*Wienerklinische Wochenschrift,* July 20, 1922) was enabled to examine fourteen additional cases of morphinism with the aid of the Hecht skin reaction (the intracutaneous injection of very dilute solutions of morphine) the results of which substantiated the findings in former examinations. Twenty-four out of twenty-nine cases examined (82.75 per cent.) were hyposusceptible to morphine. During the period of abstinence a recurrence of the susceptibility to morphine was found in nine out of thirteen cases (sixty-nine per cent.).

Serious Reactions to Repeated Transfusions in Pernicious Anemia.—Harold M. Bowcock (*Bulletin of the Johns Hopkins Hospital,* March, 1921) reports three cases of pernicious anemia in which after a large number of transfusions extremely severe reactions occurred, following the transfusion of apparently compatible blood. The cases are reported chiefly to show the inadequacy of the present method of determining the compatibility of blood for transfusion, especially when the patient has had numerous earlier transfusions. Therefore, Bowcock feels that in some cases transfusion becomes self-limited and in such instances no attempt should be made at further transfusions.

Influenza and Broncho-Pneumonia

The most disagreeable feature of these affections as they are occurring in the current epidemic, is the extreme and often dangerous depression that all too often accompanies even the mildest attack. These ills, however, have lost many of their former terrors to physicians who have learned to depend throughout their course on the tonic and supportive action of

Gray's Glycerine Tonic Comp.

Not only will this remedy bolster a weakened, flagging heart through its gratifying efficiency in promoting the assimilation of nutriment, but through its stimulation of the vital processes of the body, it will with equal efficiency, counteract the severe toxic effects of the infecting organism and thus assure an early convalescence, free from the usual complications and uncertainty.

Valentine's Meat-Juice

For **Quieting** the **Irritable Stomach** in **Pregnancy,** for **Rapidly Restoring** the **Vital Forces** in **Hemorrhage,** for **Sustaining** and **Strengthening** in **Long** and **Exhausting Labor, Valentine's Meat-Juice** is extensively employed in

Obstetrical Practice.

Dr. E. Duloroy, *Physician Accoucher to the International Hospital, Paris, France:* "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is today in good health."

Dr. Javier Ortis y Ferrer, *Physician to the Municipal Charity of Madrid, Spain:* "VALENTINE'S MEAT-JUICE has given the happiest results in cases of debility and in the asthenia produced by operations of confinements. In some cases of Tuberculosis it restored exhausted strength, and in every case where organic exhaustion manifested itself as an effect of disease."

Physicians are invited to send for brochures containing clinical reports.

Miscellany.

Colloidal Silver Salts.—Ballenger and Elder *Surgery, Gynecology and Obstetrics,* July, 1922) state that colloidal silver salts, notably the chloride, give off definite germicidal emanations. These emanations prevent the growth of microorganisms on Petrie agar plates in the immediate area surrounding the sealed glass tubes containing the colloidal silver chloride. A one per cent. preparation has a germicidal value about equal to pure carbolic acid, yet when sealed in the anterior urethra for five hours is without pain, even with much stronger preparations. No irritation is produced when applied to mucous membranes such as bladder, nose, throat and sinuses. Good results followed its application to abscess cavities, fistulous tracts, and also when used as a wet dressing for infected wounds, mastoid incisions, etc. Spermatozoa will live in a one per cent. preparation twenty minutes or longer. Being highly organized and delicate cells, this shows its relative harmlessness as a germicide. Diluted four thousand times, a five per cent. preparation killed the spirochætæ from a foul mouth in four minutes. Given intravenously to rabbits artificially infected with the staphylococcus aureus, one cubic centimetre of a one per cent. preparation cured the rabbits, sterilizing their blood within twenty-four hours, while controls, untreated, died within forty-eight to seventy-two hours with multiple abscesses of the liver, kidney, heart, and other organs.

Colloid Carcinoma.—D. Parham (*Annals of Surgery,* January, 1923), speaking of colloid carcinoma, concludes as follows: 1. In colloid carcinoma the epithelial cells possess an uncontrolled function of secreting a mucinous substance. Its accumulation is often destructive of the carcinoma cells. 2. Mucous formation is a sign of functional differentiation of the carcinoma cells, corresponding to the morphological differentiation seen in carcinomata with cells of the acinar or columnar type. 3. The mucus forming characteristics may be possessed by cells showing other morphological signs of differentiation and by those not showing such differentiation. 4. Colloid carcinomas occur in the stomach, 6.5 per cent.; cecum, 22.2 per cent.; appendix, 7.0 per cent.; transverse colon, 7.3 per cent.; sigmoid, 4.3 per cent.; rectum, 5.5 per cent; pancreas, two cases; gallbladder, 8 per cent; salivary glands, one case; bladder, 2.5 per cent.; prostate, one case; kidney, one case; ovary, 1.1 per cent., and breast, 1.12 per cent. Peritoneal carcinomata occur in 16 per cent. of all cases. 5. Colloid carcinoma is usually slow of growth and late to metastasize to glands and other organs. It often grows by permeation and may cause extensive thickening of the wall of the affected organ. 6. Local glands are often involved long before metastasis has reached distant glands. Though histologically less malignant on account of permeation of adjacent tissues, it is particularly difficult to eradicate. Death is often delayed, but the eventual mortality is greater than in other types of carcinoma. 7. Recurrence is often entirely localized to the site of origin. 8. Many patients with colloid carcinoma respond remarkably well to treatment by x ray and radium.

Chronic Universal Argyria After the Intravenous and Peroral Administration of Collargol.—Th. Tobler (*Schweizerische medizinische Wochenschrift,* August 3, 1922) reports the necropsy findings in a pronounced case of argyria following the oral administration of 0.84 gm. collargol for a month, together with thirty-eight tablespoonfuls of collargol solution and 75 c. c. of a two per cent. solution of collargol injected intravenously for cholecystitis and cholelithiasis. Most of the silver was found in the kidneys and liver; slight deposits were found in the spleen and pancreas and also in the esophagus and stomach and particularly in the intestinal tract and mesenteric lymph nodes; the tongue, soft palate, epiglottis, larynx, trachea, the large bronchi, lungs, heart and bone marrow were slightly impregnated. The cross striped muscle, nerves, cartilage and bones showed no silver granules. The uterus and particularly the bloodvessels of the tubes and ovaries showed fairly thick deposits; the same were found in the thyroid gland, especially in the interfollicular connective tissue of the lobulated portion and in the membrana propria of the duct acini of the breasts, as well as in the sweat glands of the skin. Most of the silver was in the bloodvessels, especially in the medium sized and small arteries, while the larger arteries showed no deposits. The hyaline membranes which form the framework of the glomeruli and the tunica propria of the urinary tubules and of many glands were markedly pigmented. The resorption of silver in the case reported proceeded partly from the gastrointestinal canal and partly from the vascular tract directly. With intravenous injections, a part of the silver remains in the body, especially in the Glissen capsule, the interstitial connective tissue of the pancreas, in the kidneys, spleen, bone marrow, etc. With proper doses a universal argyria need not occur; with a repeated course of silver preparations, a cumulative effect results. The duration of the administration need not be prolonged and the individual doses need not be large to produce argyria.

The Cause of Fluctuations in Respiration as Recorded by the Plethysmogram.—A. A. Weinberg (*Nederlandsche Tijdschrift v. Geneeskunde,* Haarlem, July 22, 1922) enumerates the following measurements recorded by the plethysmogram: 1. Respiratory arrhythmia, acceleration of the pulse on inspiration and slowing down on expiration; 2, decrease of volume of the bloodstream on inspiration and increase on expiration; 3, more pronounced dicrotism during expiration and decrease during inspiration; 4, the whole plethysmographic curve fell on inspiration and rose on expiration. There have been many attempts to demonstrate the relation between respiratory arrhythmia and vagus or sympathetic stimulation, and opinions vary as to the finer mechanism of the effect of respiration on the heart action. In the experiments, young healthy adult patients were chosen, as far as possible psychically and physically normal. It was observed that on inspiration the P and T waves rose and that they fell on expiration, while the R waves rose on expiration and fell on inspiration with accleration of the pulse. Variations occurred due to excitement, etc. The short pulse of inspiration was due to stronger sympathetic innervation, and the longer pulse of expiration correspond to the vagus stimulation of the heart.

Bowel Torpor in the Elderly

is usually the result of a progressive atony of the bowel, with a gradual decrease of the natural mucus and other secretions. The loss of moisture dries the feces and interferes with their free and easy passage. Under such conditions

INTEROL

serves as a safe and efficient substitute for the physiologic secretions. Following its systematic use, the bowel contents are kept soft, the intestinal canal—especially the large intestine—is adequately lubricated, and the feces are passed along and evacuated in due time without straining, pain, or discomfort.

DIRECTIONS:
In treating the elderly, begin with a tablespoonful morning and night on an empty stomach, increasing or decreasing as conditions require.

Sample and Interol brochure on request.

INTEROL thus constitutes an ideal medium for the relief of bowel torpor in patients of advanced age.

GRANDE SOURCE

The Utilization of the Complement Fixation Reaction in the Diagnosis of Tuberculous Meningitis.—Robert A. Kilduffe (*Journal of Laboratory and Clinical Medicine,* April, 1922) in the case which he reports in detail did a complement fixation test upon the spinal fluid and blood serum of the patient, reasoning on the following lines: if the reaction occurred in the spinal fluid, the antigen being biologically specific, the positive reaction would indicate the presence of specific antibodies without, however, indicating their possible source. If, however, the reaction was negative in the blood serum, knowing that the interchange of antibodies between the blood and spinal fluid occurred only in slight degree, then it seemed fair to conclude that the positive reaction in the spinal fluid arose from the presence of tuberculous infection in the meninges. A positive serum reaction would as greatly diminish the significance of a positive spinal fluid reaction as a negative serum reaction enhanced it. The tuberculous complement fixation test was positive in the spinal fluid in 1 c. c., and negative in the blood serum in 0.2 c. c. The case is reported as illustrative of a possible method of laboratory diagnosis in a condition often presenting a puzzling problem about which no mention is found in the current literature of the disease.

Fatal Hemoptysis.—A. Kristenson (*Upsala Läkareforening Förhallende,* August 5, 1922) reports in detail a case of pulmonary tuberculosis resulting in rupture of the pulmonary artery with fatal hemorrhage. The clinical diagnosis was as follows: pulmonary tuberculosis with hemoptysis; bronchiectasis; chronic bronchitis; arteriosclerosis; chronic nephritis.

The greatest interest both from a clinical and pathologico anatomical viewpoint was centred on the hemorrhage and the changes which brought it about. From the description of the microscopic material and the accompanying illustrations, it is easy to see that the rupture of the vascular wall was due to a tuberculous process of a rather acute type. The vessel wall had been approached from the outside, infiltrated with tuberculous granulation tissue and finally so weakened that it could no longer withstand the blood pressure and burst.

The blood streaming out found its way along the path of least resistance through the tuberculous and anthracotic tissues between the bloodvessels and the bronchi.

The resulting hematoma did not apparently last long and as the walls surrounding it gave no reaction, although no thrombus formation could be discovered, it passed rapidly on to the bronchial walls which, weakened by tuberculous processes, soon gave way. The hemorrhage into the bronchi must have been considerable as the blood had but a short distance to travel and through a wide passage at a pressure whose normal at this point stands at 50 mm. Hg. As a result the bronchus was so rapidly inundated with blood that the latter could not be expelled by coughing but was aspirated causing asphyxiation.

From twenty-four to seventy-nine per cent. of all cases of pulmonary tuberculosis result in hemorrhage. Out of 1,147 patients treated by the author in the tuberculosis ward of the Academic Hospital in Upsala, 540 (forty-seven per cent.) had had hemorrhage. Ten of these cases (one per cent. of all the tuberculosis cases and two per cent. of the hemoptysis cases) ended fatally, the patients choking to death from the hemorrhage. There are not infrequent cases of acute anemia following hemorrhage that go on to death in a few days. The cause of the fatal hemorrhages is in the majority of cases to be traced to an eroded vessel in a cavity with or without preliminary aneurysm. Only in exceptional cases does parenchymal hemorrhage assume such proportions. Of the ten cases of hemoptysis observed by the author, one showed a ruptured aneurysm into a cavity; in another an eroded vessel opened direct into a cavity with no sign of aneurysm; and in the eight other cases the exact point of perforation could not be found. Clinically and pathologically closely related to these hemorrhages are the intrabronchial hemorrhages due to the injurious effect of the lymph glands on the vessels in their passage through the pulmonary hilus. These often end fatally. As the cases of fatal hemoptysis in noncavernous lungs are quite rare, the author felt justified in presenting this one.

Studies on Experimental Diuresis. — K. O. Larsson (*Hygeia,* August 31, 1922) states that the object of these experiments was to gather some definite conclusion as to the intermediary currents in diuresis necessary for a better understanding of the pathosynthesis of the eclamptic symptom complex. He found that in many ways these currents were identical with those found in disturbances of the salt water metabolism of the organism. The decrease in chlorides and dilution of the blood are constant phenomena in both. The diuretics were administered intravenously to the rabbits. The first effect is a flow of tissue fluid into the blood stream. This is soon counterbalanced by the rapid fluid and chloride excretion in the extreme uresis. Thus the kidney action is dominating at first. But the kidneys soon show signs of fatigue, the blood has become considerably concentrated and thus a temporary pause in uresis is established. The flow of tissue fluid or salt and water into the blood stream continues with resulting hyperchloremia and dilution of the blood. The course of this current is therefore from the tissues to the blood out through the kidneys. It is of great importance to demonstrate that ions and cations have each their individual opposite courses in the bloodstream, and that therefore it cannot be sodiumchloride that is affected by the organic currents or excretion. This is the result of therapeutic doses of diuretics. Overdoses or toxic doses have the opposite effect and create anuria. These experiments were undertaken with the purin diuretics, caffein, teobromin, tofyllin and teocin. The author was also much interested in the effect of novasurol. Novasurol has an equal effect on sodium and chloride which is not the case with the purin diuretics. Novasurol may therefore be considered as having specific effect on sodiumchloride. This is of great importance to the author, as he may now, by careful choice of his diuretic, influence the ion current in his efforts to establish a synthesis of the eclamptic symptom complex. He prefaces his experimental reports with studies of the galvanic irritability of the nervous system as related to disturbances in salt metabolism as observed in eclampsia, nephritis, and uremia.

Influenza and Broncho-Pneumonia

The most disagreeable feature of these affections as they are occurring in the current epidemic, is the extreme and often dangerous depression that all too often accompanies even the mildest attack. These ills, however, have lost many of their former terrors to physicians who have learned to depend throughout their course on the tonic and supportive action of

Gray's Glycerine Tonic Comp.

Not only will this remedy bolster a weakened, flagging heart through its gratifying efficiency in promoting the assimilation of nutriment, but through its stimulation of the vital processes of the body, it will with equal efficiency, counteract the severe toxic effects of the infecting organism and thus assure an early convalescence, free from the usual complications and uncertainty.

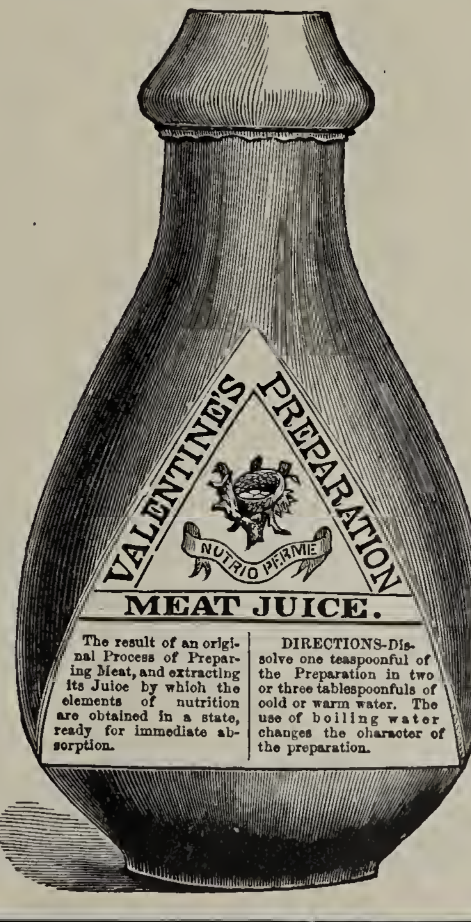
Valentine's Meat-Juice

The **Power** of **Valentine's Meat-Juice** in **Quieting** the **Irritable Stomach, Aiding** the **Digestion, Restoring** the **Appetite** and **Sustaining** and **Strengthening** has been demonstrated by many **Medical Men** in the treatment of

Anaemia, Exhaustion *and* Debility.



The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Dr. R. Sarandeses, *Physician to the Provincial Hospital, Oviedo, Spain:* "I had occasion to use VALENTINE'S MEAT-JUICE on a member of my own family and with excellent results. It is most agreeable to the sick and well, is easily prepared and administered, and for the young anæmic constitutes a superior remedy."

Dr. Lenoble, *Surgeon in Chief, Military Ward of the Hospital D'Argentan, Argentan, France:* "The powerful reconstituent, VALENTINE'S MEAT-JUICE, brought about a great improvement in the condition of the sick and wounded, whose long stay in the trenches had made them particularly anæmic."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

Miscellany.

Acute Arsenical Poisoning.—William Henry Willcox (*British Medical Journal,* July 22, 1922) finds that in poisoning with the inorganic preparations of arsenic, the gastrointestinal symptoms are the most prominent and at necropsy the arsenic is found distributed through all the organs. In poisoning by arsphenamine and allied compounds (organic), the prominent features are the poisonous effects of the arsenicals upon the organs of the body which produce the fatal symptoms; the liver bears the brunt of the attack and suffers the most damage. In fatal acute cases, marked fatty degeneration of the liver occurs and the same type of changes are seen in the kidneys and heart muscle. The symptoms of acute arsphenamine poisoning exactly simulate those of icterus gravis and the author believes that they are due to autointoxication from defective liver function consequent upon the action of the poison on the liver cells. The damage and impairment of the function must be very extensive to produce fatal autointoxication, but it does occur and therefore the changes attending the use of arsphenamine administration should always be borne in mind. The poisoning may result not only from massive administration but also from repeated doses, as shown by the occurrence of jaundice from injury of the liver weeks or months after the administration of arsphenamine, with most serious results. To avoid such a mishap, the amount of glycogen in the liver may be increased by the administration of glucose shortly before the arsphenamine is given.

Later Effects of Gas Poisoning.—T. E. Sandall (*Lancet,* October 21, 1922) presents conclusions which, in some respects, do not agree with popular impressions. He believes that if complete recovery does not take place at an early date, the later effects of gas poisoning, if not permanent, are at any rate of very long duration and lower the standard of health of the individual indefinitely. In nearly half of the cases he found emphysema, chronic bronchitis, or both, but he does not believe that pulmonary tuberculosis is a frequent sequela. He says that a certain number of tuberculosis cases give a history of gas poisoning, and that gas poisoning may perhaps stimulate latent tuberculosis into activity, but he has not seen the disease develop as a proper sequela in a single case. In nearly half of the cases there is definite tachycardia, especially in those poisoned by phosgene, yet in the great majority of these, eighty-five per cent., nothing abnormal can be found in the heart, and the causation of this condition appears to him the most important problem in connection with the subject. The persistence of gastric symptoms also raises the question of organic or functional causation. In a certain number of cases neurasthenia develops, but it is not clear whether this is due to the gas poisoning, or to the shock of the nervous system at the time of the original casualty. Another interesting point is the pain in the chest of which complaint is frequently made; is this an evidence of myocardial involvement, or is it merely a functional manifestation? With reference to prognosis he raises the question whether the element of "pension" may not operate as a factor in the causation or continuance of symptoms.

Laryngofissure for Cancer of the Larynx.—After twenty-one years of experience with the operation of laryngofissure, St. Clair Thomson (*British Medical Journal,* July 22, 1922) firmly believes that, if cancer is limited to one vocal cord and is operated on very carefully, this operation is safe as regards its execution and certain in its results. The operative mortality should be nil, a serviceable voice can be promised, and there is every prospect of a permanent freedom from recurrence. The only prerequisite is an early diagnosis.

The Theory of Inflammation.—Proceeding from Weigert's theory on inflammation, that "bioplastic" energy is liberated by the loosening of the cell cement substance as a result of the loss of constituent elements of the tissues, Ferdinand Röder (*Wiener klinische Wochenschrift,* July 27, 1922) endeavors to determine the nature of this potential energy. As a result, he proposes the following definition: Inflammation is a circulatory disturbance, usually occurring in two stages, that of the acceleration of the current and that of its retardation; the latter may be divided into two characteristic stages, that of a diminished capillary pressure and that of an increased capillary pressure.

Dangers of Rapid Intravenous Injection of Quinine Solution.—U. N. Brahmachari (*Lancet,* July 22, 1922) observed that a dangerous fall in blood pressure may result during rapid intravenous injections of solutions of quinine; the severity of the reaction depends upon the amount of quinine passing through the heart every second. Some observers also assert that the intravenous injection of large quantities of saline solution, such as a pint, may be excessive for a weak heart and therefore the question of the dilution becomes important. After conducting a series of experiments, the author concludes that in giving intravenous injections of quinine bihydrochloride, the solution of the salt should not exceed the strength of 1:300; it should be injected at the rate of ten c. c. a minute in patients over fifteen years of age. In patients below that age, the rate should be half of the one mentioned above.

Therapeutic Use of Germanium Dioxide in Anemia.—Ludwig Kast, Hilda M. Croll, and Herbert W. Schmitz (*Journal of Laboratory and Clinical Medicine,* August, 1922) treated sixteen patients suffering from anemia, administering the germanium dioxide by mouth in 0.2 per cent. water solution. Doses of between one hundred and two hundred mg. of the oxide were given daily or every two or three days until about one gram had been given. An examination of the table accompanying this paper shows that the periodical rise and fall of the red cell count after germanium, as noted by Hammett and Müller, was also seen in this series of cases. The influence of germanium or hemoglobin production was usually somewhat less marked and more delayed than its influence on red cell formation. A study of chemical blood and urine analyses in seven cases revealed no apparent effect of the germanium on the functional activity of the kidneys. In view of the fact that the germanium was found to have distinct erythropoietic action in some of these cases, it would seem worth while for this method of treatment to be further studied in a larger series of cases.

Influenza and Broncho-Pneumonia

The most disagreeable feature of these affections as they are occurring in the current epidemic, is the extreme and often dangerous depression that all too often accompanies even the mildest attack. These ills, however, have lost many of their former terrors to physicians who have learned to depend throughout their course on the tonic and supportive action of

Gray's Glycerine Tonic Comp.

Not only will this remedy bolster a weakened, flagging heart through its gratifying efficiency in promoting the assimilation of nutriment, but through its stimulation of the vital processes of the body, it will with equal efficiency, counteract the severe toxic effects of the infecting organism and thus assure an early convalescence, free from the usual complications and uncertainty.

Valentine's Meat-Juice

In **Diarrhoea, Dysentery** and **Cholera Infantum,** in the **Wasting** and **Febrile Diseases** of **Children,** and in the treatment of **Weak Babies,** the **Ease** of **Assimilation** and **Power** of **Valentine's Meat-Juice** to **Restore** and **Strengthen** has been demonstrated in Hospitals for Children.

Diseases of Children.

W. T. Watt, M. D., *Director Imperial Medical College, Tientsin, China:* "In cases of Infantile Diarrhœa, which weakens and debilitates a child rapidly, I have found VALENTINE'S MEAT-JUICE a great stimulant and quick restorative of vitality. Three years ago when an epidemic broke out in Tientsin, I ordered my staff to try your MEAT-JUICE, which justified all expectations, having been satisfactory to patients and physicians alike."

Dr. Calatraveno, *Late Physician of the Children's Hospital, Madrid, Spain:* "I have employed VALENTINE'S MEAT-JUICE most successfully in cases of convalescence from infectious diseases, and it is especially beneficial for children suffering from urinary weakness caused by extreme debility, as in every case it acted remarkably in restoring their strength with notable rapidity."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Blood Cholesterol, Its Importance, and the Value of Its Determination in Cancer Research.—Georgine Luden (*Canadian Medical Association Journal,* March, 1922) thus summarizes her paper: 1. Cholesterol is an important chemical constituent of the blood. 2. There is evidence that the blood cholesterol plays an important part by promoting cell proliferation and by combating bacterial invasion. 3. The test for cholesterol in the blood is not a diagnostic test, but it furnishes valuable information concerning the efficiency of cholesterol metabolism. 4. The activation of cholesterol metabolism after radium treatment demonstrated by the blood cholesterol determinations, and the parallel improvement of patients suffering from malignancy indicate that there is an intimate connection between disturbances of cholesterol metabolism and malignant disease. 5. Cholesterol metabolism can also be improved by dietary measures, suggesting that beneficial effects may be expected from dietary measures tending to reduce the cholesterol intake with the food, combined with radium therapy. 6. Since the life of the cells depends upon their blood supply, the chemical composition of the blood must be equally important; radium treatment changes the chemical composition of the blood, as is shown by blood cholesterol determinations. 7. Spontaneous cures have been observed in well-authenticated, inoperable, "hopeless" cases of cancer: this proves that the body can wage a winning fight against malignant disease; as therapeutic measures had proved ineffective in these cases, some internal readjustment must account for the cures. Chemical investigations will solve the cancer problem by revealing the nature of this readjustment.

The Technic of Pneumoperitoneum.—David Holmdahl (*Hygeia,* October 30, 1922) criticizes the methods used heretofore for producing pneumoperitoneum and describes a new method with distinct advantages over that of Goetz. By accidental perforation of the abdominal wall and diaphragm during three attempts at establishing pneumothorax, the author found an opportunity of studying the pressure conditions of the abdominal cavity. As a result of these observations, the author suggested the following technic for pneumoperitoneum. The patient is placed in the right lateral position with the chest somewhat elevated. The same apparatus is used as in pneumothorax. The needle is inserted from above the margin of the thorax into the left anterior axillary line pointing so far down that the eighth intercostal space is reached. When the needle has thus penetrated the diaphragm and entered the abdominal cavity, the manometer record is negative, providing the abdominal musculature is relaxed during the operation and the intestinal canal is not too full. In any case the opposite oscillation will register on deeper breathing when the needle enters the abdominal cavity. Thereupon the patient is allowed to breathe in air to the desired amount. By this method the development of emphysema of the abdominal wall may be avoided and the risk of puncturing the relatively thick, ventrical wall can be avoided by inserting the needle slowly, as one can tell by the manometer if the point has entered the abdominal cavity.

The advantages of this method are the following: 1. It does not record the negative pressure only, but also and particularly the inverted oscillation toward the pleural cavity, so that it may be ascertained with great accuracy just when the point of the needle has entered the abdominal cavity.

2. The patient need not be placed in the Trendelenburg position in order that the negative zone of the abdomen may be reached. This zone can also be reached with the patient in the lateral, horizontal position, or, better still, with the chest raised. The operation is easier when the patient is in a more natural position.

3. By inserting the needle through the diaphragm instead of through the abdominal wall certain advantages are gained. The operation is easier and safer. It is easier to judge how deep to penetrate. The abdominal musculature does not need to be punctured and must be kept relaxed throughout the operation.

The Diagnosis of Diseases of the Urinary Tract.—William C. Quimby (*Boston Medical and Surgical Journal, August* 17, 1922) suggests the following as working rules in our present state of knowledge concerning diagnosis of diseases of the urinary tract: 1. Do not rush to the use of such modern diagnostic aids as the cystoscope before having taken a detailed history of the patient and having made a thorough general physical examination. 2. Examine the urine, especially for microscopic amounts of pus or blood, but do not feel that if the urine is normal this fact excludes the possibility of disease in the urinary tract. 3. Look with the eye of a skeptic on all shadows in the plain x ray plate which seem to mean lithiasis within the urinary passages until such shadows have been proven by further measures to be in fact within these passages. 4. The accurate and early determination of the exact source of pus or blood in the urine is imperative. This can only be satisfactorily accomplished by the use of the cystoscopic and urethral catheter. 5. The data to be learned by the pyelogram are frequently of the greatest importance.

Air Embolism Following Various Diagnostic or Therapeutic Procedures in Diseases of the Pleura and the Lung.—Karl Schlaepfer (*Bulletin of the Johns Hopkins Hospital,* September, 1922) quotes a number of instances from the literature in which following various diagnostic and therapeutic procedures on the chest (puncture, irrigation of a cavity, changing tubes, introducing a probe or a rubber catheter, bismuth paste filling, decortication, thoracoscopy, fat or paraffin plombage, pneumotomy, pneumectomy) complications may ensue. These have been proved experimentally and clinically to be caused by air emboli. The clinical picture of these air emboli varies greatly, and should be made more exact by further study of the complications by means of ophthalmascopic, stool and urine examinations. The author says that the best therapy is the preventive one. When an air embolus occurs, he advises stopping the operation immediately, lowering the head of the patient, and reinforcing the heart action with stimulants. Intravenous injections of adrenalin will increase the amount of blood passing through the brain by diminishing the blood supply in the splanchnic areas (intestines, skin).

Constipation in Young Girls and Women—

especially those who spend much time indoors engaged in sedentary pursuits—is almost invariably attended by a retention of waste and toxic substances. Sooner or later these make their way from the bowel into the general system and give rise to a host of autotoxic ills.

Correction of this condition is imperative, and the safest, simplest and most effective remedy for the purpose is

INTEROL

a pure mineral oil of the proper density and viscosity to assure satisfactory lubrication of the intestinal canal, and thus relieve and correct bowel inactivity without the usual disagreeable effects of cathartics as commonly employed.

Besides lubricating the canal, INTEROL renders the feces soft and plastic, thereby promoting their easy passage and evacuation with gratifying freedom from discomfort and distress.

It would indeed be difficult to suggest any more serviceable and agreeable medium for the correction of constipation, with its attending autotoxemic conditions, than INTEROL.

Sample and Interol brochure on request.

Allied Drug and Chemical Corporation

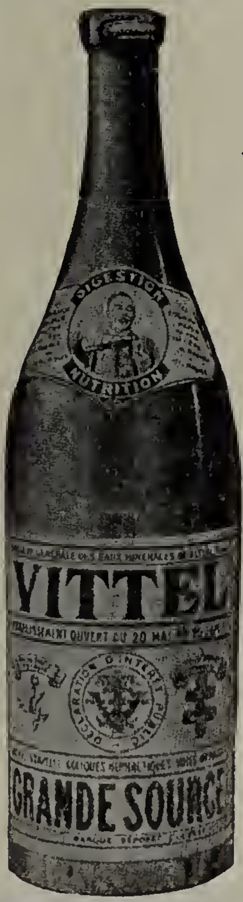
MANUFACTURERS OF ORASEPTINE—Internal and External Antiseptic, Wash, Spray and Douche.
ADACCO SALT—Effervescent Saline Laxative and Uric Acid Solvent.
VELOGEN—"The Doctor's Hand-maid and Household Emollient."

Directions:

To relieve the constipation of young girls and women, give two to four teaspoonfuls of INTEROL morning and night, increasing or decreasing the quantity as conditions require. As the bowels yield to the action of INTEROL, gradually cut down the dose to the least amount that—taken at bedtime—will assure a daily evacuation.

VITTEL

—VOSGES, FRANCE



THE mineral water of VITTEL GRANDE SOURCE recognized as of Public Utility by the French Government is refreshing, light, most agreeable to drink, essentially diuretic, and so necessary against all tendencies of arthritism: **rheumatism, gout, gravel, arteriosclerosis, high blood pressure, diabetes.** It is the surest antidote of **uric acid,** the great poison of the present generation.

Six sample quart bottles of **VITTEL GRANDE SOURCE** will be sent **Free** on request of any doctor. : :

Experimental Production of Periarteritis Nodosa in the Rabbit with a Consideration of the Specific Causal Excitant.—William H. Harris and Andrew V. Friedrichs (*Journal of Experimental Medicine,* August, 1922) produced lesions in rabbits identical with those of periarteritis nodosa by the injection into the ear veins of an emulsion of nodules from a human fatal case of the disease. The lesions consisted of exudative and degenerative processes within the walls of the smaller arteries resulting in aneurysmal formations and thromboses. They were also able to produce the lesions in rabbits injected with a filtrate obtained from an animal previously injected with the emulsion of the human nodules. They conclude that periarteritis nodosa is a specific infectious disease which is transmissible to rabbits, and that the microorganism inducing the disease belongs to the class of socalled filter passers, as it was capable of going through a Berkefeld filter N.

Dislocation of Shoulder.—T. W. Todd (*Annals of Surgery,* July, 1922) summarizes as follows: Posterior congenital dislocation of the humerus, as illustrated in the Hamann Museum at Western Reserve University, provides the following information: 1. It is of the subacromial type and differs from pathological dislocation in the fact that the humeral head never leaves the glenoid surface. 2. It results from a maldevelopment confined to the scapula and not affecting the humeral head. The maldevelopment is in the dorsal part of the scapular neck, so that the glenoid surface is rotated on to the dorsum of the blade. Accompanying this is a drooping of the acromion over the shoulder. 3. Congenital dislocation is a high grade of the deformity just described, which, however, may be of slight development and unilateral or bilateral. 4. The condition was found in three white males only among a random sequence of 730 complete human skeletons distributed as follows: 489 white males, sixty-six white females, 143 negro males, thirty-two negro females. 5. In the collection just mentioned there is no case of congenital dislocation of femur or radius. 6. Posterior congenital dislocation of the shoulder is not a true dislocation since the humeral head never leaves the glenoid surface. It is undoubtedly posterior and all the evidence goes to show that it is really congenital in occurrence since it makes its appearance coincidently with the original scleroblastic formation of the scapula. 7. There is no inherent reason why this postural deformity should not be associated sooner or later with a nerve lesion.

Persistence of Tubercle Bacilli in Expectorated Sputum.—G. Lemière (*Journal des sciences médicales de Lille,* June 4, 1922) calls attention to the fact that when tuberculosis sputum is collected in sterile test tubes, which are then stoppered with cotton, the subsequent course of events as regards the tubercle bacilli is far different from that obtaining when the sputum is discharged in unsterile receptacles and left exposed to the air. In the latter case, the tubercle bacilli are soon overwhelmed owing to the development of putrefactive germs, but in the former, putrefaction seldom occurs. The contents gradually divide into a lower solid and a supernatant fluid layer, but after ten days no further change takes place, and in the sediment tubercle bacilli are plainly to be seen even without centrifugation. These bacilli were found to remain intact in such preparations for at least fourteen months. In collecting sputum for examination, therefore, it is a good plan to use sterile test tubes to be stoppered with cotton. Further, tubercle bacilli are shown by these observations to be a potential source of danger even months after emission of the sputum.

The Morphine Habit and Its Treatment.—Margaret Vivian (*Medical Press and Circular,* November 29, 1922) says that, given a patient who is anxious to be cured, who has the average will power, and who is able to enter a medical home for a few weeks, the ideal treatment is as follows: During the first week the daily dose is rapidly cut down to two grains. It does not matter what amount he has been in the habit of taking or for how long; two grains a day will keep him comfortable and enable him to lead a normal life. When he has become accustomed to the two grains and feels no desire for more, he will begin to feel better in health, and he will eat and sleep better than he has done for years. This fact alone will encourage him to persevere. Then the daily dose is reduced by one quarter grain. The first day he may feel a little tired, but this amount is maintained until he feels that it is ample for his physical needs and he wonders why he ever took more. The procedure is repeated until a daily dose of one grain has been reached without discomfort, and it will be wise to remain at this stage for several weeks. At first one quarter grain is given four times a day, then one half grain twice a day, and finally one grain once a day, preferably on rising in the morning. The early morning is always the time when a morphine patient is at his worst, and it is advisable to continue the morning one grain dose for weeks or even months until the patient has lost all desire for the drug at any other time. From this time onward the progressive reduction must be slowly carried out. Undue haste merely leads to disappointment, and may necessitate going back temporarily to a larger dose. Even if it takes twelve months to get rid of the last grain by monthly reductions of a twelfth of a grain that is after all not an unreasonable time in which to cure a longstanding and difficult case. The patient has the mental relief of being supplied by his doctor with the necessary drug, so that there is no longer any need for him to obtain it by backdoor and expensive methods. He also has the satisfaction of cooperating in his own cure, and it is often necessary to impress on him the need to make haste slowly, so keen does he become in accelerating the pace. His health and spirits improve rapidly, and his nervous system is spared the terrible strain of the usual short cut treatment which in so many cases ends in absolute failure.

Treatment of Hay Fever.—W. C. Williams (*Military Surgeon,* October, 1921) concludes that the cutaneous test for hypersensitiveness to pollens is a simple, safe procedure and is invaluable in determining the particular pollens to which an individual may be sensitive. The treatment of hay fever by desensitizing injections of extracts of specific pollens requires accuracy and caution, and, although not always successful, it apparently offers the most rational and effective means of treating this condition.

Influenza and Broncho-Pneumonia

The most disagreeable feature of these affections as they are occurring in the current epidemic, is the extreme and often dangerous depression that all too often accompanies even the mildest attack. These ills, however, have lost many of their former terrors to physicians who have learned to depend throughout their course on the tonic and supportive action of

Gray's Glycerine Tonic Comp.

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In low forms of **Pneumonia** and **Exhaustion,** in the **General Debility** and **Depressing Prostration** following **Influenza** it is recommended by many practitioners throughout the world as invaluable in their treatment.

Pneumonia *and* Influenza.

William H. Peters, M. D., *Admitting Physician, Camp for Consumptives, State of Rhode Island, Providence, R. I.:* "VALENTINE'S MEAT-JUICE was the only nourishment retained by my five-year old daughter during an attack of Pneumonia. I consider that it saved her life and believe it to be the best product of its kind."

Cavalier Dr. Enrico Ballerini, *Late Surgeon to the Hospital of Rome, Italy:* "I have used VALENTINE'S MEAT-JUICE in the treatment of patients, and also personally, after having been very ill with Influenza, and I must say it is an excellent tonic in conditions of great organic weakness. It is also very agreeable. I have prescribed it with the greatest satisfaction for convalescents and invalids restricted to a liquid diet."

Physicians are invited to send for brochures containing clinical reports.

Miscellany.

Visceral Crises.—Arthur Mills (*British Medical Journal,* July 1, 1922) asserts that visceral crises are a manifestation of inherited and late syphilis and that they are not peculiar to tabes. No widespread syphilitic involvement of the nervous system should be attributed to tabes unless the posterior nerve roots are found involved, this alone forming the classical symptom of tabes. Visceral crises should not necessarily be included among the posterior root irritative phenomena, but should be considered as evidence of the morbid process being probably present elsewhere.

Of all the classical symptoms of tabes, root pains are probably the most constant. They are attributed to various causes, but the newer advances in the pathology of late syphilis will probably show that the crises are due to a syphilitic infection of the autonomic nervous system: the essential tissue lesion of either late or latent syphilis is a mild irritative or inflammatory process occurring in any tissue or organ, caused by the localization in the tissue of relatively avirulent spirochetes. The author reports three cases of recurrent attacks of abdominal pain and vomiting with positive Wassermann reactions, all of which respond to the therapeutic test. The classical symptoms of tabes could not be elicited.

Visceral crises are relatively uncommon in tabes (ten per cent.) but syphilitic visceral crises may be relatively frequent and may be responsible for many vague conditions, diagnostic errors and fruitless laparotomies in such cases as are diagnosed as colic, appendicular colic, kinks, bands and adhesions, and cholelithiasis without gallstones. The investigation of the knee jerks will not help, but the Wassermann test may help in clearing up the diagnosis.

The Reticuloendothelial Cells.—R. Hermann Jaffé (*Wiener klinische Wochenschrift,* July 6, 1922) states that the body contains a widely distributed cell system, which is characterized by a marked affinity for storing carmine; they also absorb colloidal substances (silver, gold, platinum, bismuth, etc.) circulating in the blood and they show marked phagocytosis, representing the fixed macrophages of Metchnikoff and playing an important part in the metabolism of hemoglobin, iron and fats. In some infections they are concerned almost exclusively with the reactive tissue changes. The reticuloendothelial system includes the following groups of cells: the connective tissue cells of Renant, the adventitious cells of the sinuses, the reticulum and pulp cells (splenocytes) of the spleen, the reticulated and endothelial cells of the lymph nodes and bone marrow, the capillary endothelia of the suprarenal glands, the spindle shaped or branched cells around the small bloodvessels, the clasmatocytes of Ranvier, the rhagiocrine connective tissue cells of Renaut, the adventitia cells of Marchand, the resting wandering cells of Maximow and the pyrrhol cells of Goldman; Lubarsch also includes the intraacinar reticulum of the pancreas and the reticulum of the thymus; in adults, the glious and the iron carrying mesenchymatous cells in certain portions of the brain may be included. These cells may separate from their cell connections and appear as free, wandering cells in the tissues and blood, forming a third group of the white blood cells, called histiocytes (Aschoff), which are easily distinguishable from the other white blood cells: after repeated injections of carmine, they show red granules in the protoplasm and resemble the large mononuclear and transition forms. They are functionally insignificant under normal conditions, but they become functionally prominent in certain diseases, such as those with increased destruction of blood (severe anemias), deep röntgen irradiation, those involving the metabolism of fat and lipoids (cholesterin), Gaucher's splenomegaly, typhoid fever, chronic infections (tuberculous, leprous and scleromatous granulations) and tropical parasitic diseases.

Observations on Catgut.—J. Fürle (*Archiv für klinische Chirurgie,* Band 119, Heft 2, 1922) states that catgut is prepared from the small intestine of goats and sheep. In the process of preparation the submucosa is the part of the intestinal wall that is used. Absolute sterility of the catgut is impossible with the methods of preparation used by the manufacturers. Of the various methods of preparation, the cumol method (Krönig), the formalin and boiling method (Hofmeister) and the iodized catgut (Claudius, Kuhn) are the best. The tensile strength is best determined by the clinical surgical utility. Resorption begins at the earliest in two to three days, but chromicized catgut has been found in the tissue after a year and a half. Infection of the tissues by catgut is the result of insufficient sterilization of the catgut, infection of the catgut by the hands of the surgeon and by the imbibition of the suture of wound germs. The biological bacteriological testing of the sterility of the catgut is difficult because of its impregnation with antiseptics. The final handling of the suture under the supervision of the surgeon responsible is very important. The prepared ligature is best preserved dry (Mikulicz, Esmarch). The very recently vaunted vacuum sterilized catgut has no advantages over the other prepared catguts.

Infection of the Sigmoid and Lateral Sinus.—H. I. Lillie (*Surgery, Gynecology, and Obstetrics,* October, 1922), from a series of nineteen cases, concludes that patients should be treated individually rather than by one routine surgical procedure. Primary operation on the jugular vein is not definitely indicated unless bleeding does not occur from the lower end of the sinus. The operation on the vein may be safely delayed, if both ends of the sinus bleed freely and the patient seems to be in fairly good condition. In none of the cases was the vein resected. Too much dependence must not be placed on laboratory findings. The general appearance of the patient is a fairly reliable index of the condition. Blood transfusion by the citrate method, care being taken properly to group the patient, is a valuable supportive measure. Unnecessary handling and examination should not be done as it annoys the patients. Forced feeding, quiet pleasant surroundings, and cheerful nursing are important factors. Patients with lung complications may recover. Thrombosis of the straight sinus may cause symptoms and signs of brain abscess. The prognosis may be said to be fairly good if well directed measures and timely surgical interference are employed.

Influenza and Broncho-Pneumonia

The most disagreeable feature of these affections as they are occurring in the current epidemic, is the extreme and often dangerous depression that all too often accompanies even the mildest attack. These ills, however, have lost many of their former terrors to physicians who have learned to depend throughout their course on the tonic and supportive action of

Gray's Glycerine Tonic Comp.

Not only will this remedy bolster a weakened, flagging heart through its gratifying efficiency in promoting the assimilation of nutriment, but through its stimulation of the vital processes of the body, it will with equal efficiency, counteract the severe toxic effects of the infecting organism and thus assure an early convalescence, free from the usual complications and uncertainty.

Valentine's Meat-Juice

In **Gastric** and **Intestinal Troubles,** in **Febrile Conditions,** in **Wasting** and **Debilitating Diseases** and before and after **Surgical Operations** when the **Stomach** is **Rejecting Food** and it is **Essential** to **Conserve** the **Vital Forces, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.**

In Hospital Practice.

P. McDonnell, *M. B. Hon. Surgeon, Lowestoft and North Suffolk Hospital, Lowestoft, England:* "We have found VALENTINE'S MEAT-JUICE invaluable in cases of shock and collapse of men who have been blown up in their ships by mines and torpedoes. Some of the patients have been severely injured, often for hours before admission here, and VALENTINE'S MEAT-JUICE has been the only food they could retain."

W. S. Tremaine, M. D., *Professor of Surgery, Niagara University; Consulting Surgeon Maternity, Emergency and St. Francis Hospitals, Buffalo, N. Y.:* "I have much pleasure in stating that I have used VALENTINE'S MEAT-JUICE for more than ten years and can testify to its excellence. I know that I have saved lives with it when every other form of nourishment was rejected. It is a most valuable preparation, and I constantly use it."

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Blood Destruction During Exercise.—G. O. Broun (*Journal of Experimental Medicine*, November, 1922) undertook the experiments reported on dogs with the object of determining whether an increased rate of blood destruction during exercise could be demonstrated. For purposes of exercise treadmills were used, constructed so that the tread was at an angle of 20°. The standard day's exercise consisted of two periods, each of two hours, separated by one hour's rest. The author found an increase in the percentage of cells and hemoglobin in the blood of the jugular vein early in the course of exercise. He interprets this as a probable result of a redistribution of red corpuscles, with an increase in their proportion in the peripheral blood. A definite increase in plasma volume was noted as exercise was continued. A coincident decrease both in the total cell volume and the pigment volume during prolonged exercise suggests that blood destruction then occurs.

Effects of Compression of the Adrenals and Blood Transfusion.—Gautrelet (*Presse médicale*, March 7, 1923) found that when pressure is made on the adrenal products of its secretion appear in the circulation and induce characteristic physiological effects. In the dog there is noted either a rise of blood pressure or the increased amplitude of beat typical of adrenalin, according as atropine has or has not been previously administered. Hyperglycemia also results. If a blood transfusion into another animal is carried out during the experiment, the second animal shows the same adrenalin effects. The same effects are even produced if a third dog is used. Upon making pressure on the adrenal in a previously bled dog, the blood pressure is no longer raised, but the increased amplitude of beats is still produced in a transfused animal. The conclusion reached is that the cardiovascular effects in these experiments are due to the adrenal secretion. The product secreted by the adrenals is not destroyed in passing into the arterial or venous systems. A physiological adrenalinemia is therefore possible.

Bronchopulmonary Lithiasis.—J. Curtis Lyter (*The Medical Clinics of North America*, July, 1922) says that the true syndrome of bronchopulmonary lithiasis results from the extrusion of a calcareous mass, formed in the bronchial or pulmonary tissues by the calcification of bronchopulmonary tissue or lymph glands, into a bronchus and out toward the exterior. The most frequent and, probably, only cause of such calcifications is chronic tuberculous infection in individuals with marked tendencies toward cicatrization and calcification. The two prime requisites for this condition are the necrosis of infected tissues and the deposition of calcium salts. Calcification also occurs in other pulmonary conditions, such as infarcts or abscess formation. Another requisite for the expulsion of stone is rupture of the surrounding fibrous capsule. The symptomatology may be *nil* because of the intactness of the enclosing capsule or the relative small size of the adjacent bronchus, or if the stone is very distant from the bronchus. The symptoms of migration or expulsion of a concretion are a slight paroxysmal cough, with slight or moderate constriction. The stone may be passed unnoticed in the sputum or it may be recognized by the patient. Severe cases show a sudden onset with pronounced thoracic oppression, poststernal pain, distress, constriction, dyspnea and a sense of anguish or tearing in the poststernal or lateral region of the chest, followed by a paroxysmal cough until the stone is either expectorated or redescends into the lower airpassages. The physical signs, which up to this time showed either a chronic disease or no evidence at all, now show evidence of pulmonary infection and infiltration and the patient is usually considered to be tuberculous. The complications usually are bronchitis, pleuropneumonia, pulmonary abscess, pyopneumothorax and sudden death from obstruction of a large bronchus. The author reported two cases wit hthe complications of pulmonary consolidation followed by pleural effusion.

Late Reaction Following Röntgen Irradiation.—Fritz M. Meyer (*Zentralblatt für Gynäkologie*, August 12, 1922) applies the term late reaction to a pathological change in the skin, which appears on the irradiated area of skin at least several months after the röntgenotherapy, without showing a radiodermatitis either during, or more or less after the irradiation. The author reports such a finding in a woman who was irradiated for a fibromyoma uteri. The skin on the abdomen was discolored brownish red throughout and showed numerous nodular elevations of the most varying size and form and also many cicatricial retractions. On the whole, the skin felt as hard as a board and showed a consistency like that of scleroderma: the skin could not be picked up in folds between the fingers. This was noticed as the earliest about seven months after the röntgenotherapy, without any dermatitis having occurred during or immediately after the treatment.

Two Cases of Bilateral Gynecomastia.—M. J. Bariliari and A. Gambetta (*La Prensa Medica Argentina*, January 10, 1922) report these cases, one in a man of seventy-six years with physiological enlargement of both mammary glands without pain or signs of inflammation, first noticed at the age of eighteen. On handling a feminine lobulation was distinctly perceptible. Sexual potency had ceased more than twenty years earlier and his external genitals seemed somewhat atrophied. Tapering feet and fingers, absence of body hair, pigmentations, a voice he said had always been shrill, and other stigmata justified a diagnosis of dysendocrinism on the part of the thyroid, pituitary, and adrenal glands, and of the testicles. The other patient also exhibited various endocrine symptoms.

Oil Ether Colonic Anesthesia by the Control Method.—Alfred E Boyd (*Irish Journal of Medical Science*, December, 1922) asserts that ether in olive oil administered by the colon produces an anesthesia characterized by an even, placid respiration of normal range, with absence of venous and capillary congestion and of mucous secretion in the throat. Danger can be avoided almost entirely by the use of the control method in which the strength of ether in the standard solution is fifty per cent., anesthesia being completed and controlled by a limited amount of oral inhalation. The success of the method depends on a strict adherence to technic.

Sluggish Bowel Action in Childhood

is usually due to errors in feeding. Subjecting these fundamentals to the customary careful correction,

INTEROL

may be administered coincidentally to relieve the immediate condition.

Dosage in Children

Begin with a half to one teaspoonful, 3 times a day before meals. Increase or decrease dose until one good movement is obtained daily. Then gradually decrease to the point where a small dose at bedtime will maintain this result.

This pure, tasteless and odorless mineral oil—notably free from the greasiness common to such products—has proved of exceptional value as a safe and dependable means of moving the bowels of young children, and this without the griping, straining and after-constipation by which the use of castor oil and other drastic cathartics is so frequently attended.

The constantly-growing number of physicians who prefer INTEROL to any other media in the routine management of constipation in early life is its own best endorsement.

Sample and Interol brochure on request.

Packing of the Nose after Operations.—Réthi (*Wiener klinische Wochenschrift,* July 20, 1922) always packs the nasal cavity after operations. He advises against the introduction of a narrow strip of gauze deeply into the nose and then packing the nasal cavity until it is filled, as this frequently does not stop the hemorrhage and may cause gagging. The main endeavor should be to compress the site of the operation by powerful lateral pressure. This the author accomplishes with the application of four to five ply strips of dermatol gauze five cm. long, which are introduced one over the other with a stout probe in several layers until sufficient lateral pressure is produced to stop the hemorrhage. When the hemorrhage has ceased, the shortest and outermost strip is removed first, followed by the successive strips nearer the wound, the last strip being removed after three to five days. The removal is painless and does not produce secondary hemorrhage.

The Postoperative Infusion of Sodium Chloride Solution Into the Peritoneal Cavity. — Albert Sippel (*Zentralblatt für Gynäkologie,* September 16, 1922) states that the routine infusion of three quarters to one litre of a warm (40° C.) physiological sodium chloride solution in connection with every laparotomy has a favorable influence upon the peritoneum. The associated advantages are: an elevation of the blood pressure, the stimulation of diuresis, the lessening of postoperative thirst and a favorable effect upon intestinal peristalsis; the disturbances resulting from the formation of adhesions and the associated postoperative intestinal obstruction resulting therefrom occur less frequently.

Epitheliomas.—F. M. Johnson (*Annals of Surgery,* March, 1922) concludes that adenoid cystic epitheliomas of the salivary gland type, occurring in the tissues of the mouth and face, are not as uncommon as the literature would indicate. Such neoplasms have been reported, but not properly recognized, and histologically interpreted. The tendency is to regard them as sarcomas. To this fact may be attributed some startling surgical cures. The characteristic tumor has slight malignant properties. Therefore it does not ulcerate and invade in its early stage. Radium treatment has been entirely successful in these cases.

Experiences in Plexus Anesthesia.—E. Platou (*Norsk Magazin for Laegevidenskaben,* September, 1922) enumerates some of the serious effects of plexus anesthesia, as reported by other authorities, and then proceeds to state the result of the method in thirty-three cases from his own observation in which twenty-six injections were performed according to the Kulenkampff method, out of which twenty-five were successful, and seven injections were performed according to Mulley's method out of which only three were successful. The technic of the Kulenkampff method consists in palpation of the subclavicular artery, insertion of a fine needle about five cm. in length immediately outside of the point where the artery bends down under the clavicle in the direction of the spinous process of the third dorsal vertebra. The author has achieved brilliant results with this technic, and feels that when carefully performed it is without danger. In many cases it is the only alternative to long continued narcosis.

Is It Worth While to Remove Aural Polypi?—J. S. Fraser and Stephen Young (*British Medical Journal,* September 9, 1922) believe that it is advisable to remove aural polypi through the external auditory meatus in the first instance in a case of chronic middle ear suppuration with aural polypi under the following conditions: 1, if there are no acute symptoms, such as earache, headache, mastoid tenderness, giddiness, vomiting, shivering, etc.; 2, if the labyrinth is found to be healthy on functional examination; 3, if it is possible for the patient to have efficient conservative treatment. If the growth occurs after efficient removal followed by careful aftertreatment, the radical mastoid operation is indicated.

Inguinal Hernia—Labat and Meeker (*Surgery, Gynecology, and Obstetrics,* March, 1922) gave a new method of field block in regional anesthesia in inguinal hernia. They conclude that regional anesthesia with novocaine adrenalin solution is the method of choice in inguinal herniotomy and should be used generally instead of only for patients who are unsafe subjects for general anesthesia. For inguinoscrotal or bilateral herniotomy in very obese patients, spinal novocainization is easier, quicker, and as safe as regional field block. A hypodermic of morphine and scopolamine one hour before anesthesia is induced is of aid in calming nervous apprehension. The patient should be informed beforehand of the method and its advantages. It is necessary that the surgeon's technic should be gentle and unhurried. Every possible detail contributing to the comfort of the patient should be utilized.

Hepatic Hormones and Essential Epidemic Hemeralopia.—J. de J. Gonzales (*Anales de la Sociedad Mexicana de Oftalmologia,* January, 1920-June, 1921) gives an account of two epidemics of essential vernal hemeralopia among the children in an asylum. The author relates the good results obtained by feeding fresh sheep and ox liver when other treatment had failed. He infers the existence of an endocrine function in the liver, engendering a hormone, which he characterizes as retinoexcitant, and which possesses the property of stimulating the production of the retinal purple, whose part in the adaptation of weak luminous intensities is well known. On this ground the hemeralopia must have been the result of a temporary hypofunctioning of the liver.

Bone Suppuration the Basic Cause of Renal Calculus in Twenty Cases Following War Wounds.—H. Ernest Paul (*Canadian Medical Association Journal,* September, 1922) finds in the twenty cases he reports evidence of a definite etiological relationship between the bone suppuration and the formation of renal calculi. He feels confident that infection is a definite contributing cause, if not the most important cause, and suggests that if every case of nephrolithiasis could be investigated with sufficient thoroughness, a history of a preceding systemic infection could be elicited. Such being the case the removal of calculus from the upper urinary tract should be considered only an important preliminary step in the cure, and treatment of the concurrent infection should be carried out thoroughly if recurrence is to be avoided.

Influenza and Broncho-Pneumonia

The most disagreeable feature of these affections as they are occurring in the current epidemic, is the extreme and often dangerous depression that all too often accompanies even the mildest attack. These ills, however, have lost many of their former terrors to physicians who have learned to depend throughout their course on the tonic and supportive action of

Gray's Glycerine Tonic Comp.

Not only will this remedy bolster a weakened, flagging heart through its gratifying efficiency in promoting the assimilation of nutriment, but through its stimulation of the vital processes of the body, it will with equal efficiency, counteract the severe toxic effects of the infecting organism and thus assure an early convalescence, free from the usual complications and uncertainty.

Valentine's Meat-Juice

In **Typhoid, Gastric** and **Other Fevers,** where it is **Essential** to **Sustain** the **Patient** without **Irritating** the **Weakened Digestive Organs, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** of **Restoring** and **Strengthening** when **Other Food Fails.**

J. R. Wood, M. D., *Physician Sheltering Arms Hospital, Paint Creek, W. Va., U. S. A.:* "I have been using VALENTINE'S MEAT-JUICE in the treatment of Typhoid Fever cases in the Sheltering Arms Hospital, for the last two or three weeks, with the most gratifying results both to the patient and physician. I consider it the best preparation of animal food I have ever seen, in fact, the only one I have ever had any success with."

Dr. Genevaix, *Assistant Surgeon-Major, First Class, Hotel Dieu, Creusot, France:* "The patients to whom I have given the excellent preparation, VALENTINE'S MEAT-JUICE, have found their general condition rapidly improved by it, and in the convalescence from continued Fever (Typhoid and Para-Typhoid) it gives the best results."

Physicians are invited to send for brochures containing clinical reports.

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Posttraumatic Calcification of the Pancreas with Diabetes.—H. G. Wells (*American Journal of the Medical Sciences,* October, 1922) reports the case of a previously healthy young man who fell from a wagon and was probably run over by at least one of the wheels. He received fractures of several ribs on the left side, traumatic infarction of the left adrenal, the upper pole of the spleen and the entire left kidney, together with a crushing injury of the pancreas, which resulted in almost complete destruction of the secreting elements, which were replaced by a large quantity of dense fibrous tissue and extensive deposits of calcium salts. Analysis showed that about sixty-four per cent. of the dry weight of the pancreas consisted of inorganic salts, chiefly calcium carbonate. Jacksonian epilepsy developed, the result of necrosis of a considerable area of the cerebral cortex, presumably occurring at the same time as the other injuries. The patient became rapidly emaciated, exhibited great thirst and the urine found in the bladder at autopsy contained sugar. A review of the literature has failed to reveal a similar case of extensive pancreatic calcification, whether posttraumatic or otherwise, or an analogous case of diabetes following crushing injury of the pancreas.

Treatment of Acute Pneumonia and Influenzal Bronchopneumonia.—W. H. Wynn (*Lancet,* September 2, 1922) believes that vaccine treatment promptly and decisively aborts pneumonia and influential bronchopneumonia and lowers the mortality if given within twenty-four to forty-eight hours. The general treatment is the same as that usually given. The vaccine is made from primary cultures or the first subcultures, not detoxicated or sensitized. In acute pneumonia, the author administers a vaccine containing several strains of the pneumococcus and in influenzal bronchopneumonia he gives equal numbers of pneumococci, streptococci and influenza bacilli. In pneumonia he gives one hundred million pneumococci to adults and in influenzal bronchopneumonia he gives one hundred millions of each organism. To a child twelve to fourteen years old, forty to fifty millions of organisms are given, and to a child two or three years old, ten to twenty millions are given. With these doses the temperature falls to normal on the following day and no further treatment is necessary. The longer the treatment is delayed, the more often must the dose be repeated every twenty-four hours until the temperature falls. After the fourth day the vaccine treatment is useless. A negative phase need not be feared in pneumonia. Antipneumococcus serum is effective, up to the present time, only in the type I cases. As large amounts of serum must be given and as these are given intravenously, general constitutional reactions often follow. To avoid these reactions, an intradermal skin test should be made before administering the serum intravenously. Foreign protein material has given good results, but the thermal reactions are too severe to justify their use when the same result is obtainable without these disadvantages. Otherwise, the usual symptomatic treatment is followed. The author does not believe in the use of alcohol because its chief action is to depress the nervous system and to inhibit the formation of antibodies.

The Effect of Body Tissues Other Than the Thyroid Upon the Basal Metabolic Rate.—J. C. Aub and M. Taylor (*Endocrinology,* March, 1922) state that three methods of testing this question suggested themselves—extirpation of various organs, feeding of dried organs or of their active principles, and injection of active principles or organ extracts. Collating the literature respecting the pituitary gland, they found that removal of the anterior lobe caused a mild reduction in the basal metabolic rate which did not develop for weeks, that feeding experiments showed no effect, and that injection of the glands had a marked influence on metabolic rate. Removal of the gonads causes in animals a rather slow fall of metabolism, amounting to about fifteen per cent. three weeks after castration. This may be due to some interrelation with the thyroid. The evidence indicates that the spleen does not markedly influence metabolism. Even severe anemia does not much affect the basal metabolic rate, but may raise it slightly. Leucemia, on the other hand, causes a very sharp increase in metabolism. Regarding the pancreas deductions from experiment are somewhat contradictory. The conclusion is not warranted that the pancreas normally acts as a depressor of the metabolic rate. In mild cases of diabetes the rate is normal; in severe cases a high protein metabolism first occurs, followed by lowering of the rate from undernutrition and emaciation. In man the liver is not a regulator of the metabolic rate. No evidence exists of thymic action upon respiratory metabolism. No definite facts have been established respecting the parathyroids. It seems clear that adrenalin and thyroxin exercise mutually independent influences in increasing the metabolic rate, adrenalin acting quickly and for minutes only, thyroxin being sluggish in onset but effective for days. Various data lead to the theory that the metabolism may be normally regulated by two mechanisms—by the adrenals for rapid variations in rate, and by the thyroid gland for more sluggish but more important changes.

Diagnosis of Early Breast Tumors.—Joseph Colt Bloodgood (*Boston Medical and Surgical Journal,* August 17, 1922) emphasizes among others the following points: 1. The examination should be made without any knowledge of the history or of the breast involved. 2. At the examination palpation is the essential feature, first, to differentiate the indefinite from the definite single lump; second, having found a definite lump to try in every way to recognize any palpable sign of malignancy. 3. At the exploratory incision the gross appearance of the growth should be observed. Unless the surgeon has sufficient experience to be certain of the benignancy from the gross appearance and frozen section, the complete operation for cancer should be performed. 4. Recurrence in the region of the scar is due to late intervention or bad surgery, usually the former. 5. To improve results there must be earlier intervention of good surgery, but good surgery will be of little avail without publicity. 6. The mistake that should never be made is an incomplete operation for cancer, it must never be in two stages. 7. The mistake that cannot always be avoided is the complete operation for cancer in doubtful cases. Bloodgood believes that when surgeons become as good diagnosticians as they are operators the number of mistakes will be reduced.

Consideration of Cancer.—J. C. Shaw (*International Journal of Surgery,* February, 1922) concludes that cancer is a disease of adult, or past middle life, and affects both men and women, white and black, rich and poor, and is most prevalent in the temperate zones. It is not considered hereditary, neither is it considered contagious nor infectious. In the beginning it is a local disease, but as it progresses, the toxic or poisonous materials are absorbed, and the general constitution is affected, as is shown by the loss of appetite, coated tongue, and a general cachexia. The etiology is not known, but the exciting cause seems to be some kind of irritation, either chemical or mechanical, which starts a new growth of epithelial cells. The conditions which predispose to cancer are age, injury or trauma, constant irritation from any cause, and any such growths as pigmented moles, warty growths, ulcers, erosions, fissures, lacerations, bruises, as of the breast, etc. The treatment is: 1. Prevention, by removal of all growths, as moles, warts or tumors which predispose to malignancy; the repair of all lacerations, as of the cervix; treatment of all fissures, chronic ulcers, etc., which are prone to become cancer. 2. Complete radical extirpation at the earliest date possible. 3. The persistent use of the x ray and radium in all cases suitable, and especially after radical extirpation. 4. All malignant cases should have good general care in every way, and in the terminal stages of inoperable cases, or operated cases with recurrence, sufficient doses of morphine should be given to relieve pain, induce sleep, and to make the patient as comfortable as possible until the end comes, as is inevitable.

Value of the Complement Fixation Test in Pulmonary Tuberculosis.—A. Lisle Punch and A. Hope Gosse (*British Medical Journal,* July 15, 1922) have previously shown that the complement fixation test is positive in ninety-eight per cent. of cases when the tubercle bacilli are present in the sputum. More recently they have shown that the two per cent. of cases in which the test is negative are those with a sudden onset and a rapid course, probably owing to the facts that the bacilli are very virulent and the invasion is massive, so that the cells which are responsible for the substances which produce the complement fixation are overwhelmed by the infection and cannot, therefore, properly respond. The rare cases, in which clinical symptoms of tuberculosis are present but the complement fixation test is negative at first but becomes positive later, are those in which a sufficient interval has not elapsed between the time of the infection and that of the elaboration of complement fixation substances. A series of control cases, consisting of healthy persons or those afflicted with nontuberculous diseases, showed negative complement fixation tests in 98.5 per cent. of cases. Of fifty cases presenting symptoms strongly suggestive of pulmonary tuberculosis but a negative complement fixation test, forty-nine showed no signs of tuberculous infection ten to twenty months later. The complement fixation test is positive before the tubercle bacilli can be demonstrated in the sputum. Owing to the uncertainty of the date of the infection, the exact interval between the invasion of the lung and the appearance of a positive complement fixation test is indeterminable. As the onset of pulmonary tuberculosis is gradual, the blood reacts positively by the time that the symptoms appear. If the onset is sudden and the test results negatively, the test should be repeated every two or three months before the diagnosis of tuberculosis is excluded. A positive test with positive pulmonary symptoms is an indication of active pulmonary tuberculosis. The test remains positive no longer than twelve months. Complementary fixation is very valuable when considered in conjunction with the clinical symptoms and it is an infallible guide to the presence or absence of active tuberculosis.

Creatine Formation in a Case of Progressive Pseudohypertrophic Muscular Dystrophy.—R. B. Gibson and Frances T. Martin (*Journal of Biological Chemistry,* December, 1921), from a study of an advanced case of progressive pseudohypertrophic muscular dystrophy draw the following conclusions from their experimental data: Ingested creatine was promptly and completely eliminated chiefly as creatine, in part as creatinine. The creatine and to a lesser extent the creatinine excretion was increased as the result of a greater protein intake. This increase is obtained only from the protein that is catabolized, including gelatin, and not from that retained for growth purposes. Preformed creatine in the diet was not an important factor to be considered in interpreting the results. Hordein, ingested sarcosine and asparagine did not lead to an increase in the creatine excretion, nor did the substitution of the arginine-rich protein edestin for 0.8 of the protein increase it.

Esophagotomy.—S. Bunnell (*Surgery, Gynecology, and Obstetrics,* March, 1923) concludes that it is possible to remove successfully the thoracic esophagus for some nonmalignant conditions and for carcinoma in a very early stage only. Great faith is necessary on the patient's part to face such an operation at a time before his symptoms have proved to him the seriousness of his condition. Still this is the only time when a removal of the esophagus for cancer can be successful. The first symptoms are usually pain and obstruction in swallowing. The pain comes when the free upward and downward excursion of the esophagus in the act of swallowing is interfered with by esophageal attachments. These symptoms denote a fair degree of advancement of the carcinoma. Diagnosis by tissue section at the onset of symptoms may make it possible to operate sufficiently early to give the patient a chance for cure.

Pin Traction in Fractures of the Forearm.—R. A. Koopmans (*Surgery, Gynecology, and Obstetrics,* December, 1922) asserts that in complicated fractures of the forearm, the pin extension method is to be preferred above other methods of treatment, because dressing of the wound is not impeded. In fractures of the forearm, with overriding of the fragments, this method of treatment deserves commendation, as the results obtained are good; in using this method, an operative reduction can be avoided.

Homatropine Cycloplegia.—William W. Lewis (*American Journal of Ophthalmology,* July, 1922) believes that his habit of prescribing a single instillation of homatropine the evening previous to the proposed examination of the eyes, done to promote a more efficient action of the drug, resulted in furnishing a danger signal in one of his patients, which enabled him to cut short an acute attack of glaucoma.

When A Tonic Is Needed

and the functions of the body are depressed and deficient, what restorative or reconstructive do you know of that will do more for the weak and debilitated than

Gray's Glycerine Tonic Comp.?

If you are not familiar with the therapeutic efficiency of Gray's Glycerine Tonic Comp., a trial in some case will show you the advantages of using a remedy that for over a third of a century has never failed in its responsibility and good faith to those it has served.

What tonic when given to patients convalescent from ***influenza, bronchitis, pneumonia, diphtheria, scarlet fever*** or ***measles,*** or from ***surgical operations,*** will so promptly stimulate the appetite, improve the digestion, increase the assimilation of food and thus restore vitality and strength, as Gray's Glycerine Tonic Comp.?

The answer to the foregoing is found in the thousands of medical men who use it regularly whenever a tonic is indicated. Their experience in countless cases has conclusively shown them that it has no superior in its field of use.

Valentine's Meat-Juice

For **Quieting** the **Irritable Stomach** in **Pregnancy,** for **Rapidly Restoring** the **Vital Forces** in **Hemorrhage,** for **Sustaining** and **Strengthening** in **Long** and **Exhausting Labor, Valentine's Meat-Juice** is extensively employed in

Obstetrical Practice.

Dr. E. Duloroy, *Physician Accoucher to the International Hospital, Paris, France:* "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is today in good health."

Dr. Javier Ortis y Ferrer, *Physician to the Municipal Charity of Madrid, Spain:* "VALENTINE'S MEAT-JUICE has given the happiest results in cases of debility and in the asthenia produced by operations of confinements. In some cases of Tuberculosis it restored exhausted strength, and in every case where organic exhaustion manifested itself as an effect of disease."

Physicians are invited to send for brochures containing clinical reports.

MISCELLANY.

Anomalous Abdominal Membranes.—A. S. Taylor (*Annals of Surgery,* May, 1922) concludes that anomalous membranes are present in from fifteen to twenty per cent. of newborn infants. They result from atypical peritoneal fusion during fetal life. Many of them are probably modified by later pathological changes due to continued traction, irritation, or low grade inflammation. They occur in the hepatoduodenal region, at the duodenojejunal angle, and about the cecum, ascending colon, hepatic flexure and beginning transverse colon. Two or more of these regions are involved in the majority of individual cases. Groups of cases illustrating the results of treatment of the membranes found in the individual locations have been published by various men: hepatoduodenal group by Harris; duodenojejunal groups by Kellogg; and pericolic group (Jackson's membrane) by Jackson, but sufficient emphasis seems not to have been put upon the fact that two or more of these lesions exist in the majority of individuals who fall within the whole large group. They cause mechanical disturbances, fixation, angulation, compression and torsion of the digestive tract resulting in partial, continuous, and often increasing obstruction. This, in turn, frequently causes dilatation proximal to the obstruction. Symptoms result when the obstruction becomes greater than the peristaltic efficiency can easily overcome. This balance may be gradually lost over a long period of time, with resulting slowly increasing symptomatology. It may be suddenly lost as the result of a prostrating injury or illness, the obstruction remaining constant while the viscus, becoming atonic, is no longer competent to overcome it. Sometimes the viscus regains its relative power and the symptoms improve.

For a long time it was thought that these cases developed symptomatology only after twenty years or more of age. The investigations of Kerley in infants and children suffering from malnutrition, cyclic vomiting, recurrent acidosis, etc., show that abdominal examination and studies of the barium gastrointestinal series give precisely the same findings as do the older patients in whom operation has demonstrated the lesions, and caused cure in a high percentage of cases. This would indicate that symptoms appear in definite form at any period of life when the balance of peristaltic efficiency against the partial obstruction is lost. The symptomatology consists of: Digestive disturbances previously described; general nutritional disturbances; nervous debility, usually termed neurasthenia (and occasionally mild psychosis). At some period the appendix is likely to become tender to pressure, is assumed to cause the symptomatology by reflex action, whatever that may be, and is removed, with failure to cause improvement. There are usually tender spots in the midepigastrium, over the appendix, over cecum and ascending colon, and over the duodenojejunal angle, depending upon the presence of the various lesions. There is varying dilatation and ptosis of the stomach, and varying dilatation of cecum and ascending colon. In marked obstruction at the duodenojejunal angle the dilated duodenum can be made out. Examination of gastric contents and stools gives no evidence of value as a rule. The most important element of evidence is found in the barium gastrointestinal series. It must be a good series, with sufficiently frequent plates. The plates must be read by one experienced in these cases. It is common to receive typewritten reports that the plates are negative or that the digestive tract is normal when inspection of the plates shows characteristic evidence to be on the plates. Fluoroscopy should be done by one experienced in these cases, especially to determine the presence of obstruction at the duodenojejunal angle, indicated by marked distention of dependent duodenum, with writhing and rushing of the contents back and forth. The pictures are not quite so conclusive, and on the operating table the duodenum may be empty and the condition not so obvious.

The plates are likely to show: Hepatoduodenal membrane: The stomach dilated, ptosed, with varying peristaltic activity, with or without retention. The apex of duodenum fixed high, sharply angulated and showing little mobility. The cap is often deformed but not in the way characteristic of ulcer. The second part of duodenum is likely to be compressed and narrowed. Duodenojejunal angle obstruction: Dependent duodenum, if dilated, may or may not show definitely on the plates. Pericolic membrane: The hepatic flexure shows high fixation (often near the duodenal apex), angulation, and often transverse colon descends in contact with ascending colon. Cecum and ascending colon are dilated. Ascending colon often showing constriction at about its middle. Appendix, if still present, usually retains the barium for long periods. Ileocecal valve is often incompetent. Treatment: a, Prolonged medical. b, Surgical. Best incision is transverse right rectus, as it gives best exposure of the whole field, and postoperative adhesions are in least troublesome situation. c, Postoperative, abdominal massage, supervision of diet, and general hygiene.

Suture of Ruptured Left Dome of the Diaphragm.—C. Jennings Marshall (*British Medical Journal,* June 3, 1922) reports the case of a youth who was thrown from a bicycle and who, in addition to other injuries, showed a complete and striking absence of dyspnea. The mechanical condition simulated pneumothorax—lung collapse, mediastinal displacement, air in the pleural cavity, although it was enclosed in bowel. The loudness and superficial character of the rare borborygmi were nearly conclusive evidence of a hollow viscus in the thorax; there was also a succussion splash, induced by a jerk in the epigastrium. The heart did not return to its normal location. Operation by rib resection in the axilla resulted in no respiratory disturbance. The exposed omentum seen on opening the thorax was found with the greater curvature of the stomach which was distended and below it were the transverse colon and several coils of small intestine; the left edge of the liver just projected into the pleural cavity. The viscera were replaced with the aid of the elevation of the head and the removal of a supporting sandbag in front of the abdomen. The edges of the rent were freshened and sutured under little tension. Convalescence was uninterrupted. The röntgenograms showed the diaphragmatic outline to be irregular and ill defined; above it, up to the second intercostal space, there was a translucent area, typical of gas within a distended viscus. The stomach appeared in the thoracic cavity.

Bowel Torpor in the Elderly

is usually the result of a progressive atony of the bowel, with a gradual decrease of the natural mucus and other secretions. The loss of moisture dries the feces and interferes with their free and easy passage. Under such conditions

INTEROL

serves as a safe and efficient substitute for the physiologic secretions. Following its systematic use, the bowel contents are kept soft, the intestinal canal—especially the large intestine—is adequately lubricated, and the feces are passed along and evacuated in due time without straining, pain, or discomfort.

INTEROL thus constitutes an ideal medium for the relief of bowel torpor in patients of advanced age.

DIRECTIONS:

In treating the elderly, begin with a tablespoonful morning and night on an empty stomach, increasing or decreasing as conditions require.

Sample and Interol brochure on request.

GRANDE SOURCE

Myokinetic and the Myotonic Function and the Diseases of the Tonicity of Muscle.—J. Pal (*Wiener klinische Wochenschrift,* September 21, 1922) differentiates between the kinetic and the functional elements of the function of muscle. The energy of motion consists of a cellular and an intracellular motion, which are of unequal value under different conditions. The intensity and extent of the cellular motion, aside from the innervation, also depends upon the tonus substrate, which is produced by a hypothetical working stock (energy) substance and composed of various elements. Muscle tonicity is the palpable expression of the peripheral accumulation of this working stock substance. The increase of the latter is a prerequisite of hypertrophy and its increase leads to atrophy. Changes in the tonus substrate (induced by congenital asthenia, intoxication and anomalies of internal secretion or of metabolism) form the basic conditions of the "diseases of tonicity," which may be either general or local, transient or permanent diseases of muscle.

Vaccination Treatment of Osteomyelitis.—A. v. Beust (*Schweizerische medizinische Wochenschrift,* August 31, 1922) obtained no true successes with vaccination in his cases with the smaller dose as advised by Grégoire. The vaccination is a valuable aid in the usual surgical treatment under certain conditions, but not in every case. The author believes that additional experiments should be conducted, particularly with more concentrated vaccine, as used by the French authors. In this way better and more significant results may be obtainable.

Scope of Vaccine Therapy.—C. E. Jenkins (*Lancet,* September 9, 1922) divides all cases that are suitable for vaccine therapy into three groups: Group I cases depend upon two cardinal principles: the bacterial origin of the disease and the preparation of the vaccine from the causal organism. Other subsidiary factors are that the patient's condition be capable of improvement, the age of the patient, the opportunity for rest and an adequate resistance of the patient. Alcoholic excesses are a predisposing cause of bacterial invasion. Another type of case that is often benefited by vaccine therapy is the sufferer from a disease in which only the secondary infection or complication is treated, leaving the primary cause to be taken care of by Nature, as in valvular disease of the heart complicated by chronic bacterial pulmonary infection. "Open" pulmonary tuberculosis is another type. The isolation of the causal organism may be simple or difficult, depending upon the difficulty in the identification of causation rather than in the obtaining of a growth, as in conditions of the intestinal tract. Group II includes conditions that govern the composition and use of prophylactic vaccines, in which it is essential that the vaccine should contain all the organisms likely to cause infection and also several strains of each organism. The duration of immunity is a minimum of twelve months. If recurrence occurs, it is of a milder type and of shorter duration. Group III includes catarrh of the respiratory passages, especially after an acute attack. The vaccine in such a condition should cover all the organisms commonly encountered as infective agents in the respiratory tract, including both those of the immediate infection as well as a good multistrain stock vaccine of the other organisms (semiautogenous vaccine). Such a vaccine is indicated in chronic rheumatism and in rheumatoid arthritis.

In vaccine therapy a constitutional disturbance should be avoided. The doses should be arranged so as to cause only a few hours of a "tired feeling" and the intervals between doses should be five to seven days. The number of injections should not exceed eight. The final improvement appears three weeks to one month after treatment has ceased. A second course may be given only after four to five months. The author prefers the residual vaccine to the old type of simple vaccine. Vaccine therapy should not be used as a last resort, but should be combined with other treatment, as in acute or chronic gonorrhea. The semiautogenous vaccine should also be used as a preliminary to surgical therapy to increase the prospects of success in operative work.

Symptomatology, Pathogenesis, and Radiotherapy of Erythremia.—Franz Högler (*Wiener Archiv für Innere Medizin,* April 5, 1922) was enabled to observe clinically five cases of erythremia, which showed a series of rarer symptoms in addition to the usual ones. He is opposed to the common clinical classification of this disease into the types of Vaquez, Gaisböck, Mosse and those with leucemic phenomena, and bases his conclusions only on the hyperplasia of the erythropoietic apparatus, on the basis of his clinical observations and of the pathologicanatomic findings as the cause of erythremia. The blood findings were reduced to normal or almost normal in all of the five cases by the application of highly active radium preparations to the bones; all of the other disease symptoms of erythremia also disappeared almost completely without special general disturbances. In one case the improvement lasted almost two years, when a recurrence set in, but a renewed treatment of the erythropoietic apparatus led to a complete cure without the occurrence of any disturbances.

Carcinoma of Breast. — Gage and Adams (*Annals of Surgery,* September, 1922) assert that no time limit can be set beyond which recurrence may not occur. Absence of malignant infiltration of axillary glands warrants much more favorable prognosis. Any lump in the breast is to be regarded with suspicion and carefully watched. Its persistence, and especially its activity, as indicated by increase in size, is ground for its removal, though not necessarily involving removal of entire breast. A continued discharge from the nipple means a pathological condition in the breast, must be kept under close observation, and be regarded with suspicion.

Bile in Blood.—DeWitt Stetten (*Annals of Surgery,* August, 1922) states in conclusion, that the icterus index determination is of value from the surgical viewpoint. 1. As an indicator of the absence or presence of jaundice and as an aid to diagnosis in doubtful cases, being more dependable and delicate than the inspection of the skin and sclera, or the examination of the urine. 2. As a method of accurately estimating, in frank icterus, the preoperative or postoperative increase or decrease in the degree of jaundice with the accompanying progression or recession of the disease. 3. As a guide in differential diagnosis, in the placing of operative indications and in prognosis, in cases of outspoken jaundice, by means of the study of the fluctuations in the index figures.

When A Tonic Is Needed

and the functions of the body are depressed and deficient, what restorative or reconstructive do you know of that will do more for the weak and debilitated than

Gray's Glycerine Tonic Comp.?

If you are not familiar with the therapeutic efficiency of Gray's Glycerine Tonic Comp., a trial in some case will show you the advantages of using a remedy that for over a third of a century has never failed in its responsibility and good faith to those it has served.

What tonic when given to patients convalescent from ***influenza, bronchitis, pneumonia, diphtheria, scarlet fever*** or ***measles,*** or from ***surgical operations,*** will so promptly stimulate the appetite, improve the digestion, increase the assimilation of food and thus restore vitality and strength, as Gray's Glycerine Tonic Comp.?

The answer to the foregoing is found in the thousands of medical men who use it regularly whenever a tonic is indicated. Their experience in countless cases has conclusively shown them that it has no superior in its field of use.

Valentine's Meat-Juice

In **Typhoid, Gastric** and **Other Fevers,** where it is **Essential** to **Sustain** the **Patient** without **Irritating** the **Weakened Digestive Organs, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** of **Restoring** and **Strengthening** when **Other Food Fails.**

J. R. Wood, M. D., *Physician Sheltering Arms Hospital, Paint Creek, W. Va., U. S. A.:* "I have been using VALENTINE'S MEAT-JUICE in the treatment of Typhoid Fever cases in the Sheltering Arms Hospital, for the last two or three weeks, with the most gratifying results both to the patient and physician. I consider it the best preparation of animal food I have ever seen, in fact, the only one I have ever had any success with."

Dr. Genevaix, *Assistant Surgeon-Major, First Class, Hotel Dieu, Creusot, France:* "The patients to whom I have given the excellent preparation, VALENTINE'S MEAT-JUICE, have found their general condition rapidly improved by it, and in the convalescence from continued Fever (Typhoid and Para-Typhoid) it gives the best results."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.

The result of an original Process of Preparing Meat, and extracting its Juice by which the elements of nutrition are obtained in a state, ready for immediate absorption.

DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Milk Transmission of Pollen Hay Fever.—Edgar T. Herrmann (*Minnesota Medicine,* March, 1923) reports that previously sensitized guineapigs react by anaphylactic shock to intrathecal injections of milk containing ragweed pollen extract. Ragweed pollen containing milk gives a positive cutaneous reaction in high dilutions in sensitive individuals. Ingestion of milk from a cow which has eaten ragweed tops produces clinical hay fever within an hour after ingestion of the milk. Absence of gastrointestinal symptoms following one glass of milk and the appearance of selective anaphylactic phenomena in the upper respiratory tract may be due to chronic irritation and decreased resistance of the tissues involved. Ragweed pollen protein is found apparently unchanged in the milk of cows that have eaten ragweed tops some hours earlier.

Clinical and Pathological Study of Tonsils Subjected to X Ray.—Charles R C. Borden (*Boston Medical and Surgical Journal,* April 5, 1923) reports upon fourteen cases of diseased tonsils x rayed from one to four times which failed to show any clinical or pathological change, except that during the period when radiation was being given some tonsils seemed to be smaller. However, on removal by dissection there was no real change in size. After radiation many tonsils looked normal in size and color, but at operation a number of them were found to be filled with pus or cheesy débris. As a method of reducing bleeding and assisting in dissection at the time of operation, radiation is useful. By diminishing oversecretion from the mucous surfaces of the throat it decidedly decreased the possibility of postoperative pneumonia or lung abscess following throat operations. In cases where diseased tonsils may be justly suspected of producing secondary infection in the joints, heart, kidney or other important organs, x ray radiations are inadequate.

Action of Vaccines.—J. Pratt-Johnson (*Lancet,* October 7, 1922) states that marked anaphylaxis or hypersensitiveness to the related bacterial vaccine is found almost invariably in acute local and general infections and may be present in a lesser degree, or may be absent in chronic infections. Sensitiveness to vaccine may be demonstrated by inoculation of a minute dose of vaccine which is followed shortly by local, focal, and general effects. Such a dose is without effect on a healthy individual or on a subject not suffering from the infection, but the positive result can be seen in acute infections of the respiratory tract. Prophylactic injections of vaccine in a healthy subject produce excess of antibodies and frequently an associated leucocytosis: Where the causative microorganism develops an unusually high degree of virulence, as in a severe epidemic, a cautious prognosis is necessary; the antibody titre cannot invariably be accepted as evidence of established immunity in an inoculated subject. The action of vaccine employed prophylactically in individuals recently recovered from an acute attack or suffering from a latent infection, consists of a preliminary desensitization with small doses gradually increased until doses sufficiently large are employed to ensure a satisfactory antibody response. The severe reaction following the use of large prophylactic doses in individuals still sensitive to vaccine is actually due to a change in the patient or hypersensitiveness. In chronic infections, the injection of the antigen or vaccine gives rise to an overproduction of antibodies and a varying degree of leucocytosis. With minute doses in acute local infections, the vaccine produces a desensitization of the patient to the bacterial toxins generated by the infecting microorganisms. The repetition of the same dose is followed by diminishing effects and a gradual increase in doses is necessary to keep pace with the desensitization process until the dose is sufficiently large to be effective during the convalescence for the production of antibodies. The principle of the reaction is the same as that of protein desensitization and the action of the vaccine is similar in acute general infections and in acute local infections. The local reaction is best studied by making the inoculation superficially into the subcutaneous tissue and the size of the dose and the interval between doses are determined by the size and duration of the reddened area. A general reaction consists of a fall of temperature and sweating for six to twelve hours after inoculation, followed by the alleviation of symptoms and, frequently, a restful sleep. Intravenous injections of vaccine should be confined solely to chronic infections.

Effect of Bismuth on the Kidneys.—H. B. Day (*Lancet,* August 12, 1922) encountered certain toxic effects following the intravenous injection of bismuth, which are not usually mentioned in the literature. He used the liquor bismuthi et ammonii citratis (B. P.), which contains about nine per cent. of bismuth citrate. This was put up in sterile ampules. Injections of 0.5 or 1.0 c. c. had no general effect, but on repetition a black line formed on the gums with a stomatitis (sometimes), the condition resembling a mixed effect of lead and of mercury. But intravenous injections, especially with large doses of two c. c., produced no signs of poisoning; there were nausea or vomiting and slight diarrhea in most of the cases, but the most striking effect was a copious diuresis, without strangury or other signs of vesical irritation. When it was given in two cases of actual nephritis, one patient improved as a result of the diuresis and the condition of the other patient remained unchanged—neither improved nor aggravated.

Hemolytic Streptococcic Infections in Children.—I. H. Erb (*Canadian Medical Association Jaurnal,* January, 1923) says that most cases occur during the months of January to April. Males are more commonly affected than females. Nearly forty per cent. of all cases were fatal. Almost eleven per cent. of deaths from all causes are due to infection from this organism. Infants are very susceptible, thirty per cent. of all cases occurring in babies under six months old. In the bronchopneumonia cases empyema developed in forty-four per cent. of the patients of whom forty per cent. died. In ninety per cent. of the cases of peritonitis the patients died. Over fifty per cent. of the deaths followed tonsillitis, nasopharyngitis, or otitis media. Erysipelas in infants is frequently associated with septicemia and is usually fatal. Practically all cases of umbilical infection are fatal.

In Hot Weather Breast Milk Saves Babies

In view of the campaign to encourage breast feeding every mother should be impressed with the value of human milk in the prevention of bowel troubles. The hot spell will soon be here and now is the time to begin with your educational work to encourage breast feeding.

A clean, nourishing, easily digested food is the only kind of food for the baby when breast milk is not available. Eagle Brand Milk meets all of these requirements.

Osmotic Drainage in Therapeutics.—Doumer (*Bulletin de l'Académie de médecine,* February 27, 1923) applies this term to a procedure calculated to rid mucous membranes or infected tissues of pathogenic matter which may be present in the intercellular spaces and which cannot be reached by antiseptics. Any hypertonic solution of a substance which is neutral, saline or organic, and devoid of caustic, may be used for the purpose. Simple syrup is convenient and acts powerfully. The treatment was first used in a case of blepharitis of eight years' standing, against which all forms of treatment except the static effluve had failed, even this measure proving too troublesome to be continued. Congestion involved not only the lid margin but also the conjunctiva and sometimes the sclera. The lid margins were greatly thickened and there was intense photophobia and a constant sensation of heat in the lids, with secretion sufficient to glue the lids in the morning. The treatment applied was to instil a drop of simple syrup in each eye every evening and place a small compress well moistened with it along each palpebral fissure. The syrup caused marked burning for a few minutes, and after it passed off a drop of fluid, containing expelled white concretions from the glands of the lids, exuded from the outer canthus. Even after the first application the photophobia and sensation of heat were markedly improved, and by the third day the patient was able to read, the thickening of the lid margins and conjunctival hyperemia meanwhile disappearing. After three weeks the treatment could be stopped without return of the preexisting congestive manifestations.

Thrombosis of the Coronary Arteries With Infarction of the Heart.—Joseph T. Wearn (*American Journal of the Medical Sciences,* February, 1923), from studies on nineteen patients observed in the Peter Bent Brigham Hospital, constructs the following as a picture of the typical case: We will find a patient, usually a man, possibly less frequently a woman, past forty and probably over fifty, complaining of severe pain over the heart or under the lower end of the sternum, or almost as frequently of pain in the epigastrium. Less frequently the complaint may be of a sudden attack of extreme shortness of breath, persistent and unrelieved by rest. The patient may have been in good or fairly good health the minute before being seized by an excruciating pain in the region of the precordium or in the epigastrium, which usually radiates into the shoulders and down one or both arms. Unlike angina attacks, which may have been experienced before, it persists for hours or days and relief at times seems impossible. Extreme dyspnea accompanies the pain, or may occur alone. The attack may come after exertion, or the patient may be asleep at the time. Closely following the pain and dyspnea may be nausea, vomiting, weakness, and even collapse. The skin is pale ashen in color, moist and cold. The face presents an intense expression of anxiety and suffering. A few signs of edema may be heard in the lungs. The heart is moderately enlarged and very weak. The liver is likely to be enlarged and may or may not be tender. Fever and a polymorphonuclear leucocytosis occur with sufficient constancy to make them of definite value in recognizing the condition.

Recent Cancer Therapy. — Francis Carter Wood (*Canadian Medical Association Journal,* March, 1923) sums up his excellent discussion of what is now known concerning the therapy of cancer by advising operation in all cases of operable malignant growths. He says that to treat such a growth by radiation methods assumes that we know the exact amount of radiation necessary to kill all the cancer cells, but this we positively do not know at the present time for human tumors. The assumption that if a part of the tumor is killed by radiation the body cells will destroy the rest is pure phantasy without the slightest foundation either in clinical observation or experimental work. If the body tissues had any power to destroy carcinoma cells, a malignant tumor would be destroyed in its inception, and the fact that it is not is definite proof of the lack of any such protective capacity. In borderline and doubtful cases a combination of radiation and surgery is often the most effective. The type of radiation to be used depends upon the site of the tumor, the extent and nature of the surgery upon the same factor. Inoperable carcinoma should be treated with radium if small and fairly well localized; with the x ray if extensive. Operation is useless in inoperable cases and tends to make the patient worse rather than better. In many cases no palliative effect is obtained from any form of radiation; in others the tumors seem to be of low biological resistance and remarkable palliative effects are obtainable, which may last for a considerable period of years, accomplishing a result in a condition before which surgery is powerless. The hope of making extensive inroads into the death rate of cancer lies in publicity, to bring the patients early to the surgeon. The task of the surgeon is to improve his technic and extend his operative field so that all of the tumor can be removed as promptly as possible. If this cannot be accomplished, we have in radiation an extraordinary palliative measure which prolongs life and adds to the comfort of the patient. If no cures were ever obtained by either radium or x ray, their use would be justifiable on account of the valuable palliation they often offer.

A Method for the Permanent Sterile Drainage of Intraabdominal Ducts, as Applied to the Common Duct.—Peyton Rous and Philip D. McMaster (*Journal of Experimental Medicine,* January, 1923) report a method by which the total bile may be collected in a sterile state day after day, during months and probably for years. The success of the method lies in the interpolation, with special care for asepsis, of a long drainage tube between the common duct and the opening in the abdominal wall. The tube must be pliable near the cannula, or the latter may be pushed askew through leverage exerted by the viscera, with obstruction as result; it must be resistant where it passes the abdominal wall to sustain muscular contraction. To fulfill these requirements a curved glass tube is used with, on one limb, soft black rubber tubing that connects with the cannula, and on the other, a piece of red duodenal tubing that is to pass through the abdominal wall. The entire U of rubber and glass should be as long as the abdominal cavity will readily permit—ten to twelve cm. in a large animal. If a short tube is used it will regularly come away after a few days.

Dioxogen

H_2O_2 12v

owes its action entirely to the large volume of pure, uncontaminated oxygen it provides at exactly the place where it is required.

The value of oxygen as the most effective and safest of purifying and antiseptic agents needs no comment, but its liberation explains not only the efficiency of Dioxogen in destroying germs and promoting wound healing, but also its absolute freedom from toxic or irritating effect.

Assuring, therefore, dependability of action with perfect safety, Dioxogen unquestionably holds the place it does today in the everyday practice of medicine and surgery, because of its manifest advantages over other germicides.

Gradually, but surely it has become the routine antiseptic in the doctor's office, the dispensary, the hospital clinic, factory, school and home.

Because --

First —It is not only the most effective but the safest of antiseptics.

Second — It accomplishes its germicidal action entirely by the pure nascent oxygen it liberates —Nature's own antiseptic.

Third — It is odorless, tasteless and practically free from impurities.

Fourth —It is colorless, and does not stain the skin or dressings.

Fifth — It is not only non-poisonous and non-irritating to the tissues, but through the large volume of oxygen it gives off, it is a powerful stimulant to healing and repair.

Uses--

As an antiseptic — For cuts, lacerations, abrasions, and all open wounds.

As a lotion — For ivy poisoning, sunburn, chafes and skin irritations.

As a spray and gargle— For colds, sore throat, eye infections, and as a mouth cleanser.

As a compress — For strains, sprains, contusions and swollen muscles.

As an internal remedy—For gastro-intestinal ills, diarrhea, etc., from changes in food and water.

*This vaccine was in druggist's stock in the regular way and recalled as outdated.

ENDO INTRAVENOUS SOLUTIONS

WHEN solutions that are isotonic with the blood are injected intravenously they become one with the blood, gravitate with it and carry the medicament to the cells and tissues that require it.

Solutions that are either of lower or higher osmotic tension than the blood separate quickly from it and are flushed through the kidneys. The medicament is eliminated with the urine in a few hours.

To prevent "laking" of the cells and to obtain the maximum of therapeutic action with the minimum amount of drugging, intravenous solutions should be isotonic with the blood.

Endo-intravenous solutions are prepared with the thought in mind that the best is not too good for the sick.

Endo Solutions Are Isotonic

"—the Discovery of Ehrlich and Benda is fast becoming the recognized Antiseptic!"

WHEN Ehrlich discovered the therapeutic properties of aniline dyes—and when Benda later developed Neutral Acriflavine—a definite advance was made in progressive therapeutics.

All branches of the medical profession are utilizing the superior antiseptic value of Neutral Acriflavine which actually increases in contact with serum or other organic matter. Of all the antiseptics in common use, Neutral Acriflavine has the greatest therapeutic co-efficient (Browning) and yet, because it is neutral, it is non-irritating.

Most of its power is concentrated on the parasites and not on the tissues of the human body (Hahn and Remy).

Let us send you a pamphlet outlining the advantages of Neutral Acriflavine and containing numerous reports from medical authorities.

AGAR-AGAR
As a Vehicle in
Intestinal Therapeutics

In intestinal disturbances it is advantageous to apply a remedy that will cover a large area before being absorbed. This can be conveniently accomplished by using agar as a medicinal vehicle. For an agar-containing remedy will first absorb fluid and later liberate the medicinal substance through osmosis. This process takes place slowly, and in this way a large area of the intestines will take up the medicinal agent which has escaped from the agar through osmosis.

Another property of agar which is advantageous, is its power of retaining fluids and thus increasing the bulk of and also partly softening the feces.

We manufacture ten different preparations, for the treatment of intestinal ailments, using agar as a vehicle, and will gladly send descriptive literature to physicians.

KELLOGG'S BRAN

for the relief of constipation

RELIEVES CONSTIPATION
Kellogg's
BRAN
READY TO EAT
THE ORIGINAL HAS THIS SIGNATURE
W. K. Kellogg
KELLOGG COMPANY
BATTLE CREEK, MICH. AND TORONTO, CAN.
Kellogg's
BRAN

In mild or chronic constipation cases, the value of bran, as you know, lies in its bulk. Distention of the intestine provides improved peristaltic action, which gives the anticipated relief.

Physicians everywhere are prescribing Kellogg's Bran and advocating its daily use at the family table, because Kellogg's is ALL BRAN. The point is made that the required bulk is not obtainable in foods with a partial bran content. Relief would be delayed and suffering and annoyance prolonged.

The mechanical action of Kellogg's Bran is exceedingly positive because it is ALL BRAN and it may be prescribed with confidence in both chronic and mild cases.

Patients find Kellogg's Bran delicious in flavor and edibility. Kellogg's should not be compared with common bran!

Physicians are asked to mail a request card to Kellogg Company, Battle Creek, Mich., and a full-sized package of Kellogg's Bran will be forwarded without obligation.

An Analysis of
Kellogg's BRAN

Aside from its regulatory value, Kellogg's Bran commands attention as one of the most valuable foods known. Read this analysis:

Study Pepsodent

Scientific data on request, based on 7 years of tests

Pepsodent is based on the acid theory, as expounded by numerous modern dental authorities.

Thorough application brings a mild acid into contact with the mucin plaque, wherever it exists. There it acts to disintegrate plaque at every stage of its formation, as acids will.

Mild acid also increases the salivary flow, and reduces its viscosity. It increases the alkalinity of the saliva. It increases its ptyalin content, for digesting starch deposits on teeth.

These are natural results which right diet might bring, but which Pepsodent increases and insures.

No soap—no chalk

Pepsodent contains no soap, no chalk. It complies with the dominant modern dental opinion by omitting all alkaline products.

Alkalis, of course, bring just opposite effects. They make the plaque more viscid and more clinging. They reduce the alkalinity of the saliva, and reduce its ptyalin index.

The polishing agent in Pepsodent is a blend of calcium phosphate and anhydrous calcium sulphate, both in finely powdered form. In their pure form, as we use them, they are ideal polishing agents.

Facts now accepted

For seven years Pepsodent has been the subject of clinical and laboratory tests. Thus the following facts have been proved so well that dentists in general accept them.

1—That Pepsodent effectively combats mucin plaque. It acts to disintegrate it, to curdle or flake it, at every stage.

2—That its polishing agent is uniquely efficient in removing all forms of deposit.

3—That its mild acid reaction increases the natural tooth-protecting agents in the mouth.

4—That the acid is harmless. Natural teeth have been immersed for four years in Pepsodent mixed with saliva without evidence of harm.

5—That the polishing agent is not severe. It is far softer than enamel. Natural teeth have been brushed with Pepsodent up to 250,000 times without any sign of abrasion. Absence of soap lubrication makes the polishing agent somewhat conspicuous, but that agent does not harm.

Why so important

Pepsodent is used by millions. You see constant evidence of its good effects and are often asked about it.

It is advised by leading dentists the world over, and by a growing number, we believe. Careful people of some 50 nations now employ it.

It conforms to the theories which dominate now, and which promise to become universal.

You desire full knowledge of such a product, and the facts are at your command. Please send the coupon for them, and for a tube to try.

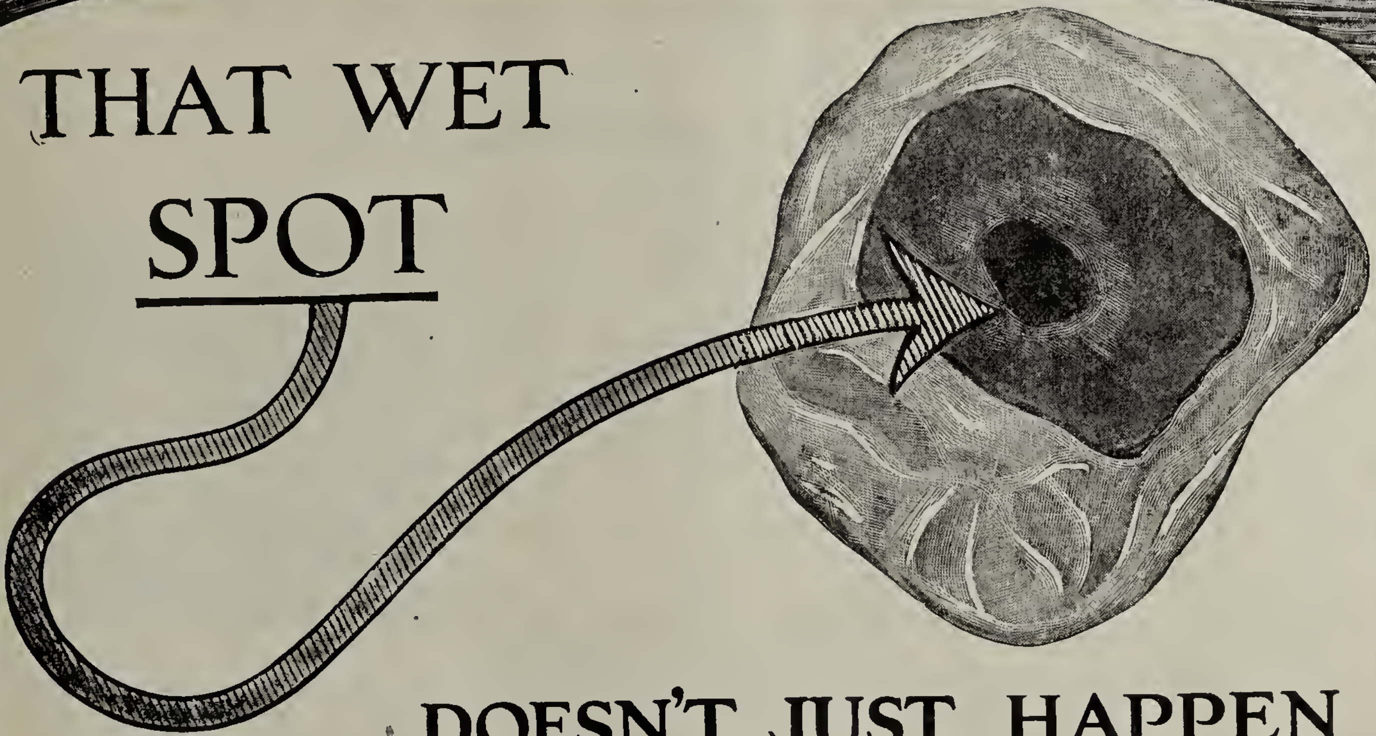
THAT WET SPOT



DOESN'T JUST HAPPEN

THE PHENOMENON EXISTS in obedience to a fixed law—OSMOSIS—and is visible proof that Antiphlogistine has been operating scientifically.

The Antiphlogistine Poultice, some hours after its application to an inflamed area, reveals (on removal) certain phenomena.

The center is moist, where exudate has been drawn from the congested tissues—while the periphery, covering normal surrounding tissues is virtually dry.

Liquids follow lines of least resistance. The skin acts as a porous membrane separating two fluids of different densities—Antiphlogistine and the blood. An interchange occurs between their fluid constituents, endosmotic or exosmotic according to the direction of least resistance.

Lubrication in Colitis

An enterologist of international repute calls attention to the value of liquid petrolatum in colitis. In connection with such routine measures as proper diet, he finds that liquid petrolatum aids greatly in soothing the irritated surfaces and, through softening the intestinal contents, helps to overcome the spastic condition of the intestine.

Chronic colitis, dilatation of the catarrhal right colon, the whole viscus in irritation as shown by the excessive peristalses throughout. Fermentative type of toxemia present.

From "Diseases of the Digestive System," by Anthony Bassler, M.D., F. A. C. P. Published by F. A. Davis Co., Philadelphia.

NUJOL is highly efficacious in all types of intestinal stasis and resulting disorders. It is used in practice by many leading enterologists.

In determining a viscosity best adapted to general requirements Nujol Laboratories tried consistencies ranging from a thin fluid to a positive jelly. The viscosity adopted was fixed upon after exhaustive clinical test and research and is in accord with the opinions of leading medical authorities.

That the value of Nujol to the medical profession is generally recognized is attested by its use by physicians and in hospitals the world over.

Sample and authoritative literature dealing with the general and special uses of Nujol will be sent gratis.

Paget—A Simple Treatment for Tuberculosis

Every conscientious physician in the world would rejoice to know of a simple and effective treatment for tuberculosis. Whether Dr. Paget's entirely novel treatment is applicable to any of your present patients is a matter no one can decide better than yourself, after careful reading of this little book. Duty to yourself and to your patients will suggest that you make no decision *before* reading.

Dr. Owen Paget is a British physician, a Cambridge man, now in practice in Western Australia. During war service in England hundreds of Australian Army tuberculosis cases were in his care and received his truly simple treatment, which, in brief, is nasal insufflation of a bacillary emulsion, based upon the bactericidal functions of the upper nasal passages.

The book has an Introduction by Professor J. George Adami, of Liverpool University, formerly professor of General Pathology and Bacteriology at McGill University, Montreal, and well known to American physicians, who says that what finally led him to support Dr. Paget was the fact that "while among the Australian soldiers in the tuberculosis wards there were three deaths in the fortnight before his treatment was undertaken, during the ensuing ten months, with treatments, there were only two deaths among the 500 and more admitted to those wards, on the diagnosis of other medical officers, as suffering from tuberculosis." Dr. Paget of course offers much other evidence, and Dr. W. P. Birmingham has written a preface in which he tells of treating fifty cases in his general practice, with rapid recovery in early cases, and great improvement in advanced, hopeless cases. Dr. Birmingham strongly recommends his fellow-practitioners to adopt Dr. Paget's methods. Every physician who ever treats tuberculosis cases should at least study this volume carefully. It is just a little book of 80 pages, price $1.75. Owing to the demand, the trifling cost, and the fact that the entire contents can be absorbed in an hour, copies can not reasonably be sent on approval.

Laboratory Studies in Tropical Medicine

By C. W. Daniels, M.B., F.R.C.P., formerly Director of the London School of Tropical Medicine, and H. B. Newham, C.M.G., M.D., Director of the London School of Tropical Medicine. New fifth edition, thoroughly revised, octavo, 590 pages, 184 illustrations, 7 colored plates.

Pathologists, bacteriologists, physicians located in tropical countries, public health officers, students, and all interested in the investigation and diagnosis of tropical disease will welcome a new edition of the work of such well known authorities. Prof. Daniels' previous work on Tropical Medicine and Hygiene has rendered great service.

Hale-White—Selected Passages from Laennec

Sir William Hale-White, M.D., believes that Laennec's *"L'Auscultation Médiate"* has had a greater influence on modern medicine than any other book. The present small volume is intended to be an introduction to Laennec, hence the biography is short, but the selected passages translated contain nearly all that the great physician wrote on diseases of respiration. The book will quickly be found in every medical library of importance, and in the possession of all who enjoy the study of medical history. 203 pages, illustrated, $3.75 net.

NOW READY International Medical Annual, 1923

The 41st year of this famous Annual Review of the World's Progress in Medicine and Surgery, by thirty-two eminent international specialists. This incomparable volume should be in the hands of every physician and surgeon. It is worth a good deal more than five dollars to you for the up to date authoritative reviews of your own specialties alone. 556 pages, 43 illustrations, 48 plates (some colored). Subscription, $5.00 net.

Lejars—Urgent Surgery (For Surgeons and General Practitioners)

By Felix Lejars, Professor of Clinical Surgery, University of Paris. New third English edition, translated from the eighth French edition (revised and enlarged), by W. S. Dickie, O.B.E., F.R.C.S., and Ernest Ward, M.A., M.D., F.R.C.S. Super Royal octavo, two volumes in one, 840 pages, 1088 illustrations, plain and colored, 20 full page plates, $16.00 net.

The new translation of the latest edition of this very important work should be found in the library of every surgeon, and every general practitioner who is at any time liable to be confronted by emergencies demanding immediate surgical interference. Prof. Lejars' famous book has been published in Japanese and five European languages. The former English translations were very highly valued throughout the English-speaking world. The French edition is in two volumes, but this translation has been combined into one large handsome book, magnificently illustrated. The surgeon specialist will find it an illuminating treatise on acute operative surgery, a true picture of French technical methods by one of the great French master surgeons. At the same time the directions are so explicit that the country physician or surgeon, or even the recent graduate could hardly go wrong with this invaluable book as his guide.

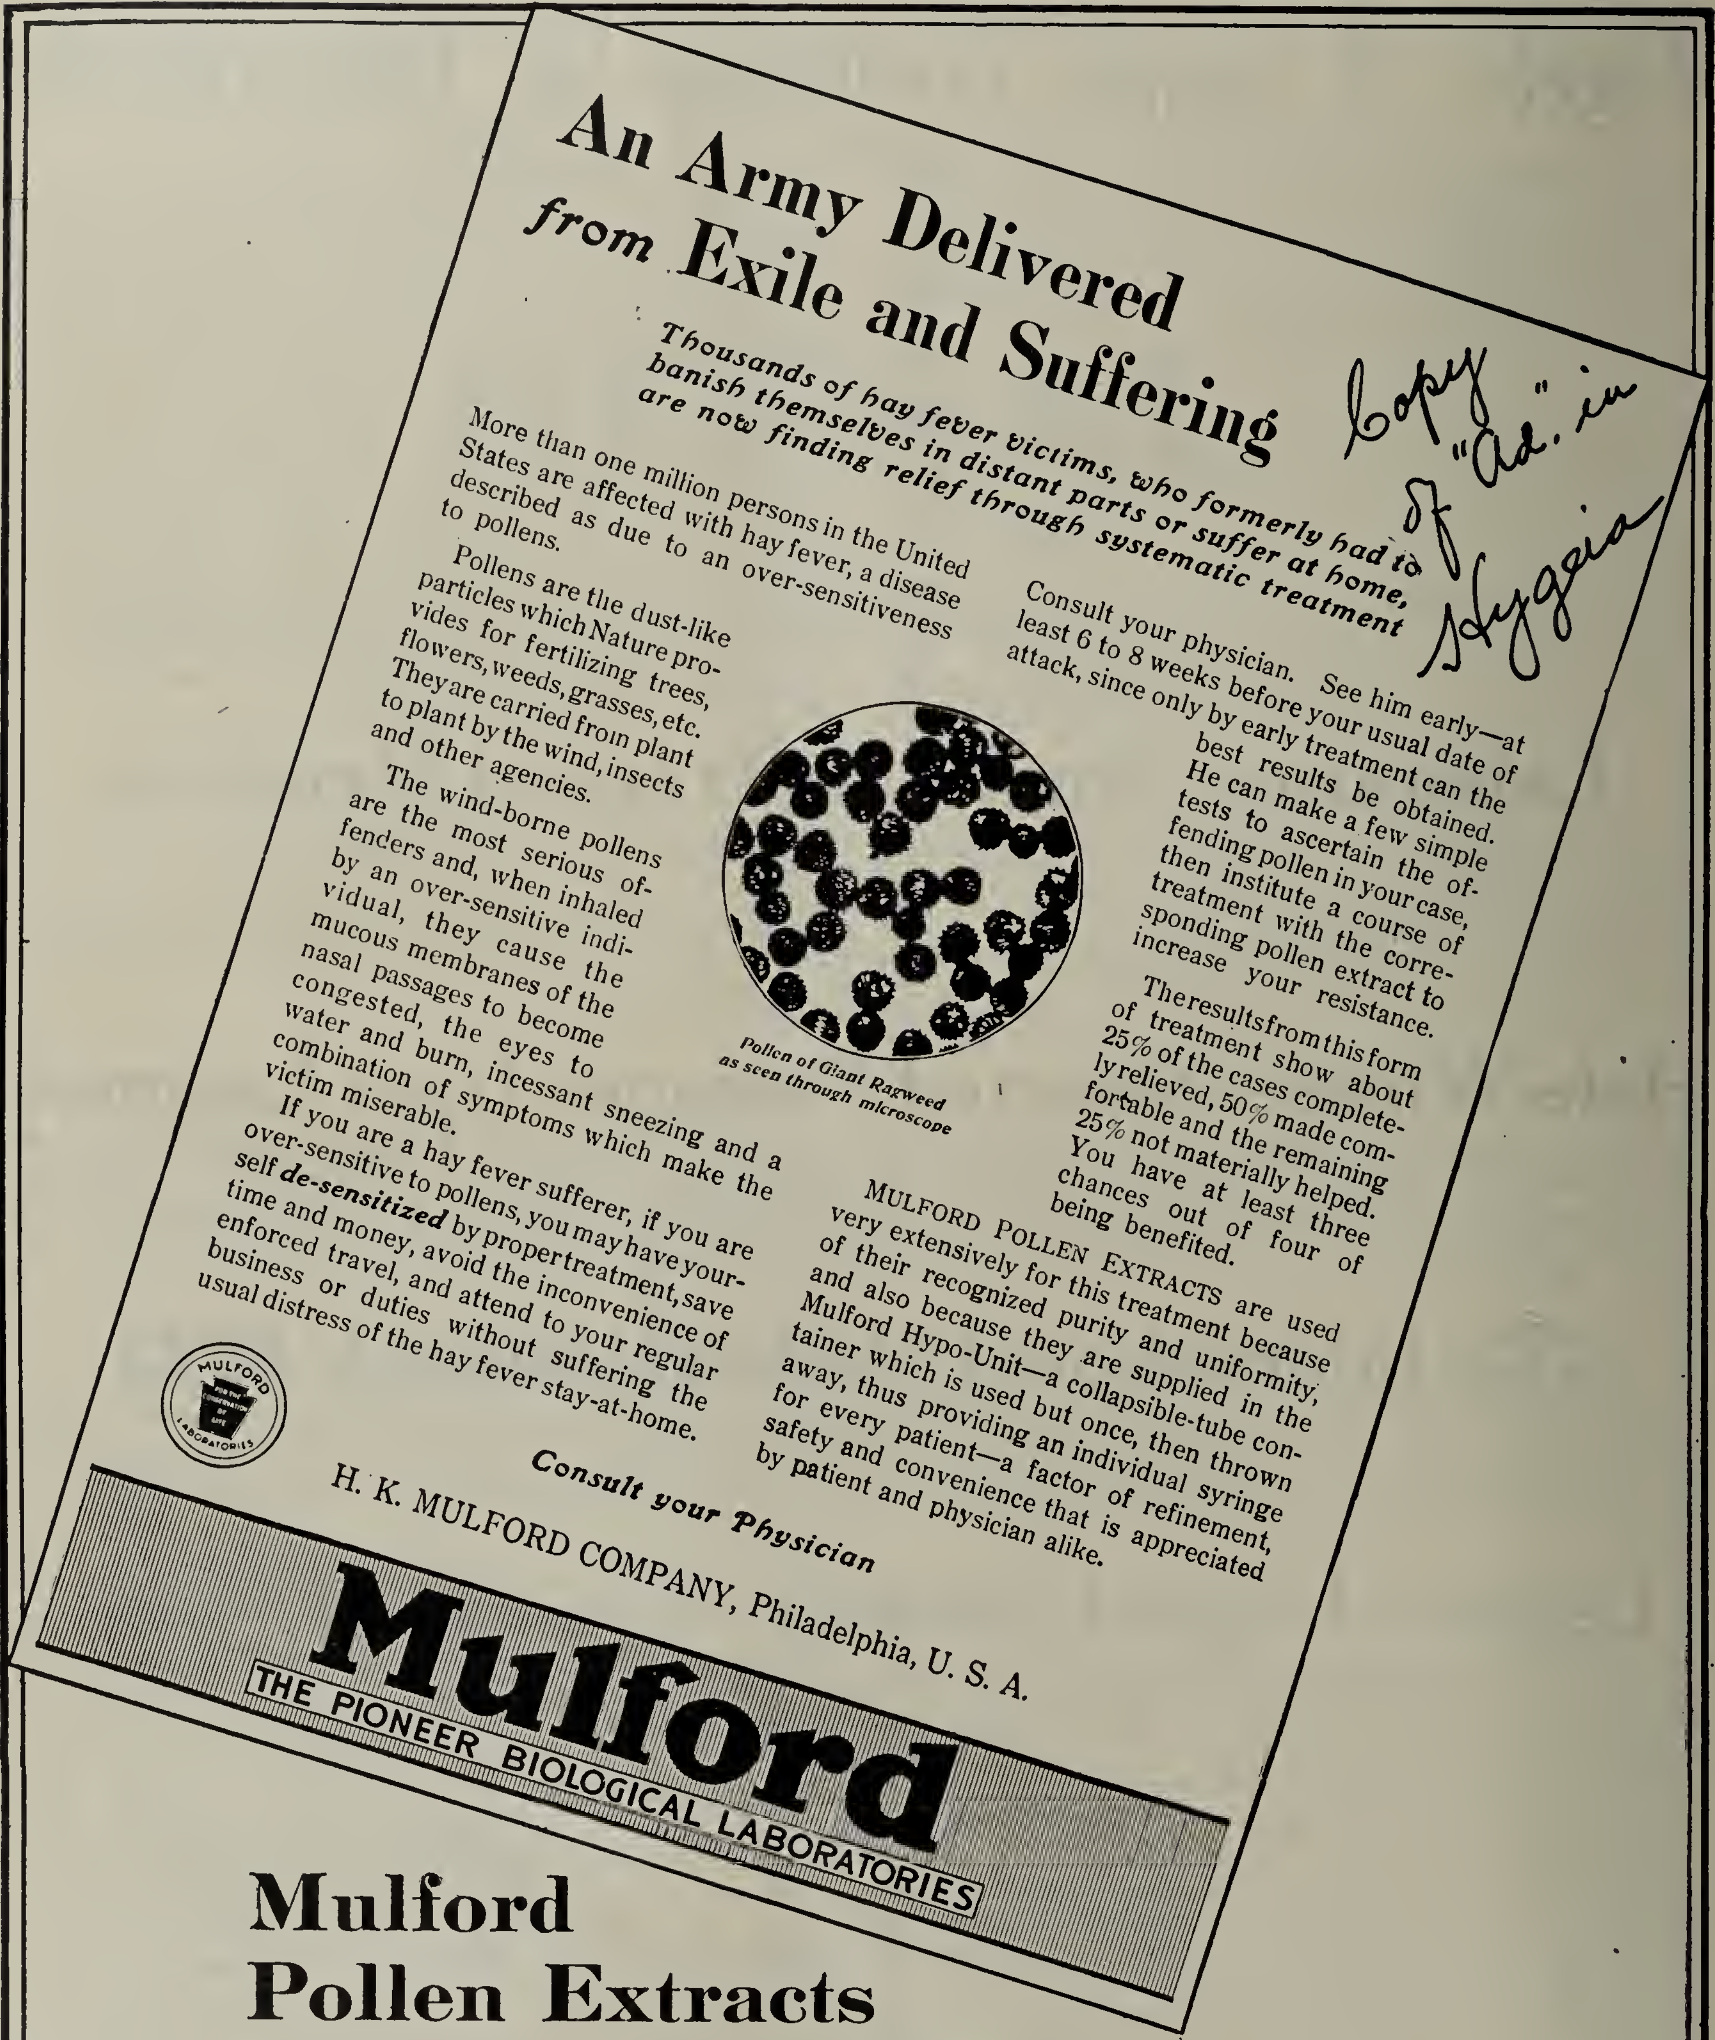
"Is easily the best work on emergency surgery, the most popular, the most interesting, the most replete with valuable practical hints and observations."—*Amer. Jour. Surgery.*

"It will prove of interest not only to medical men whose isolation obliges them to rely on themselves but also to surgical specialists. The work will continue to rank among the best works on surgical technique in any language."—*New York Medical Journal.*

Reference Handbook of the Medical Sciences

Send for the free prospectus of the new fourth edition of this great encyclopedia. Its 445 contributors are America's leading authorities. As a matter of personal and professional pride and efficiency you should own this invaluable aid. You will need very few other medical books.

WILLIAM WOOD & CO. (*Est. 1804*) **51 Fifth Ave., New York**



An Army Delivered from Exile and Suffering

Thousands of hay fever victims, who formerly had to banish themselves in distant parts or suffer at home, are now finding relief through systematic treatment

More than one million persons in the United States are affected with hay fever, a disease described as due to an over-sensitiveness to pollens.

Pollens are the dust-like particles which Nature provides for fertilizing trees, flowers, weeds, grasses, etc. They are carried from plant to plant by the wind, insects and other agencies.

The wind-borne pollens are the most serious offenders and, when inhaled by an over-sensitive individual, they cause the mucous membranes of the nasal passages to become congested, the eyes to water and burn, incessant sneezing and a combination of symptoms which make the victim miserable.

If you are a hay fever sufferer, if you are over-sensitive to pollens, you may have yourself ***de-sensitized*** by proper treatment, save time and money, avoid the inconvenience of enforced travel, and attend to your regular business or duties without suffering the usual distress of the hay fever stay-at-home.

Pollen of Giant Ragweed as seen through microscope

Consult your physician. See him early—at least 6 to 8 weeks before your usual date of attack, since only by early treatment can the best results be obtained. He can make a few simple tests to ascertain the offending pollen in your case, then institute a course of treatment with the corresponding pollen extract to increase your resistance.

The results from this form of treatment show about 25% of the cases completely relieved, 50% made comfortable and the remaining 25% not materially helped. You have at least three chances out of four of being benefited.

MULFORD POLLEN EXTRACTS are used very extensively for this treatment because of their recognized purity and uniformity, and also because they are supplied in the Mulford Hypo-Unit—a collapsible-tube container which is used but once, then thrown away, thus providing an individual syringe for every patient—a factor of refinement, safety and convenience that is appreciated by patient and physician alike.

Neutral Acriflavine Abbott

(Made under license from The Chemical Foundation, Inc.)

This reliable Abbott-quality drug is now ready

Supplied in handy tablets of 0.46 grain each for preparing solutions. In enteric coated tablets especially for oral use. Also as the pure chemical, in glass vials of 1 Gram each, for making solutions. The crystalline powder may also be had in bottles of 5 and 25 Grams respectively.

Neutral Acriflavine, Abbott, is a drug of superlative purity, **yielding perfectly neutral and non-irritating solutions.** Indications are that it is fully as efficient as the parent drug and, in the sense that stronger concentrations may be employed, even more efficient.

For use in the urethra. For wound treatment. For oral use as a urinary antiseptic. And for other therapeutic purposes for which the drug has been recommended by American and European clinicians.

Descriptive leaflet sent on request.

If your druggist cannot supply you with **Neutral Acriflavine,** Abbott, send your order direct.

Presented in bottles of 20 tablets at $0.50 net and in bottles of 100 tablets at $2.00 net. Enteric coated tablets in bottles of 100, $2.00 net; and in powder at the following net prices: 1 Gram, $0.50; 5 Grams, $1.85; 25 Grams, $8.75.

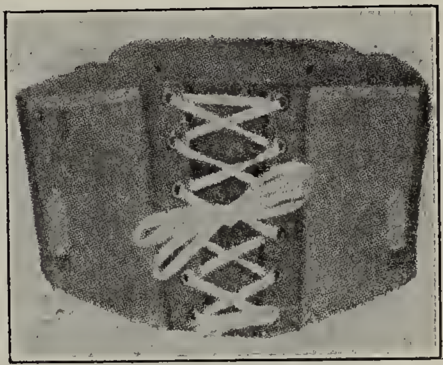
FRONT VIEW

Sacro-Iliac Belts

"THE MAYO"



BACK VIEW

The Mayo Sacro-Iliac Belt is the most satisfactory appliance for controlling and relieving Sacro-Iliac sub-luxation. This belt has now reached an advanced stage, and we are bringing it to the attention of the Medical Profession, for the recognition that it deserves.

This Belt is constructed of heavy six inch orthopaedic webbing, with a separate abdominal plate, providing for its correct adjustment, with a suitable sacral pad attached and covered with chamois. This appliance gives the desired support when properly adjusted.

The belt should be tightly buckled in front on each side, before direct pressure is secured over the sacrum by the lacings which are provided at that point. Examination of the cuts will give a good idea of its construction and superior points.

The price is $12.00. Take measurement around the hips three inches below the Iliac crests, or directly over the trochanters.

Campho-Phenique

A POWERFUL GERMICIDE

A host of germicides command attention through sheer merit. Any one that stands out among them with particular conspicuousness does so because of exceptional value and because it has demonstrated its superior worth beyond question.

CAMPHO-PHENIQUE rules among its kind because it is superior to them in actual searching tests. As a germicide CAMPHO-PHENIQUE is positive in effect, economical and uniform in action.

As a first aid dressing CAMPHO-PHENIQUE is the logical choice, owing to its continuous germicidal action and anodyne effect.

The properties possesed by Campho-Phenique make it the ideal dressing for all surgical wounds. It prevents infection and hastens healing.

Keep a supply of CAMPHO-PHENIQUE on hand for all antiseptic purposes.

Samples mailed on request.

Campho-Phenique Co., St. Louis, Mo., U. S. A.

MERCUROSAL SUBJECTED TO PHYSIOLOGICAL TEST

AFTER every practicable chemical test has shown Mercurosal,* the new anti-syphilitic mercury compound, to be satisfactory, this product is subjected to a test for toxicity on rabbits of standard weight, these animals having been found to yield more definite data than others.

Mercurosal in solution is introduced into the marginal vein of the rabbit's ear at a carefully controlled rate—very slowly depending on the size of the animal. The optimum rate of injection has been determined by numerous experiments, and is an important item in the test.

Our investigators will not pass any batch of Mercurosal that will prove fatal to a 2- to 4-kilo rabbit in a dose of less than 40 to 80 milligrams. The standard is a minimum of 20 to 30 milligrams per kilo.

The margin of safety is impressive. Calculated on the basis of weight alone a toxic dose of Mercurosal for a man weighing 65 kilos (150 lbs.) would be 1.3 gms. or *13 times the recommended intravenous dose.*

By means of the chemical tests we determine the purity of Mercurosal, and from that might be judged its relative freedom from toxicity; nevertheless the physiologic toxicity test is invariably performed as an added precaution.

*Disodiumhydroxymercurisalicyloxyacetate. Contains about 43.5% of mercury in organic combination. Relatively non-toxic and non-irritating. Adapted for intravenous and intramuscular administration in the treatment of syphilis.

PARKE, DAVIS & COMPANY

MENSTRUAL AND
MENOPAUSAL DISORDERS

afford a good field for appropriate organotherapy. It is now recognized that pluriglandular combinations give better results than single gland products. Clinical results emphasize this and physicians who use

HORMOTONE

are seldom disappointed. In those women at the menopause whose thyroid function diminishes too quickly with a consequent high blood pressure and other disagreeable symptoms

Hormotone Without Post-Pituitary

is recommended. Both products have the approval of many leading physicians.

INTEROL

may be administered coincidentally to relieve the immediate condition.

This pure, tasteless and odorless mineral oil—notably free from the greasiness common to such products—has proved of exceptional value as a safe and dependable means of moving the bowels of young children, and this without the griping, straining and after-constipation by which the use of castor oil and other drastic cathartics is so frequently attended.

The constantly-growing number of physicians who prefer INTEROL to any other media in the routine management of constipation in early life is its own best endorsement.

Dosage in Children

Begin with a half to one teaspoonful, 3 times a day before meals. Increase or decrease dose until one good movement is obtained daily. Then gradually decrease to the point where a small dose at bedtime will maintain this result.

Sample and Interol brochure on request.

McK & R

The Babies Will Be Thankful For The Comfort Of McK & R Compound Stearate of Zinc

THE heated season is particularly hard on babies. Acid discharges in the perspiration tend to cause chafing, eruptions, and irritative skin conditions. "Diaper rash" is more frequently met with than in colder weather—the skin being more susceptible to the excoriating effects of urinary and fecal discharges.

You can minimize all these troubles for the babies, Doctor, if you will recommend the liberal use of McK & R Compound Stearate of Zinc.

After the bath, Compound Stearate of Zinc, applied as a routine measure, tends to overcome prickly heat, and skin discomforts generally.

A liberal dusting with McK & R Compound Stearate of Zinc, around the genitals and in the tissue folds, will render the local surfaces moisture-proof, and prevent the irritation following acid discharges. Do not forget Compound Stearate of Zinc as a valuable aid in preventing and overcoming sunburn, in adults as well as children.

If you are not already familiar with McK & R Compound Stearate of Zinc, send your card for literature and samples of this valuable product.

McKESSON & ROBBINS

Digestive Disorders of All Seasons

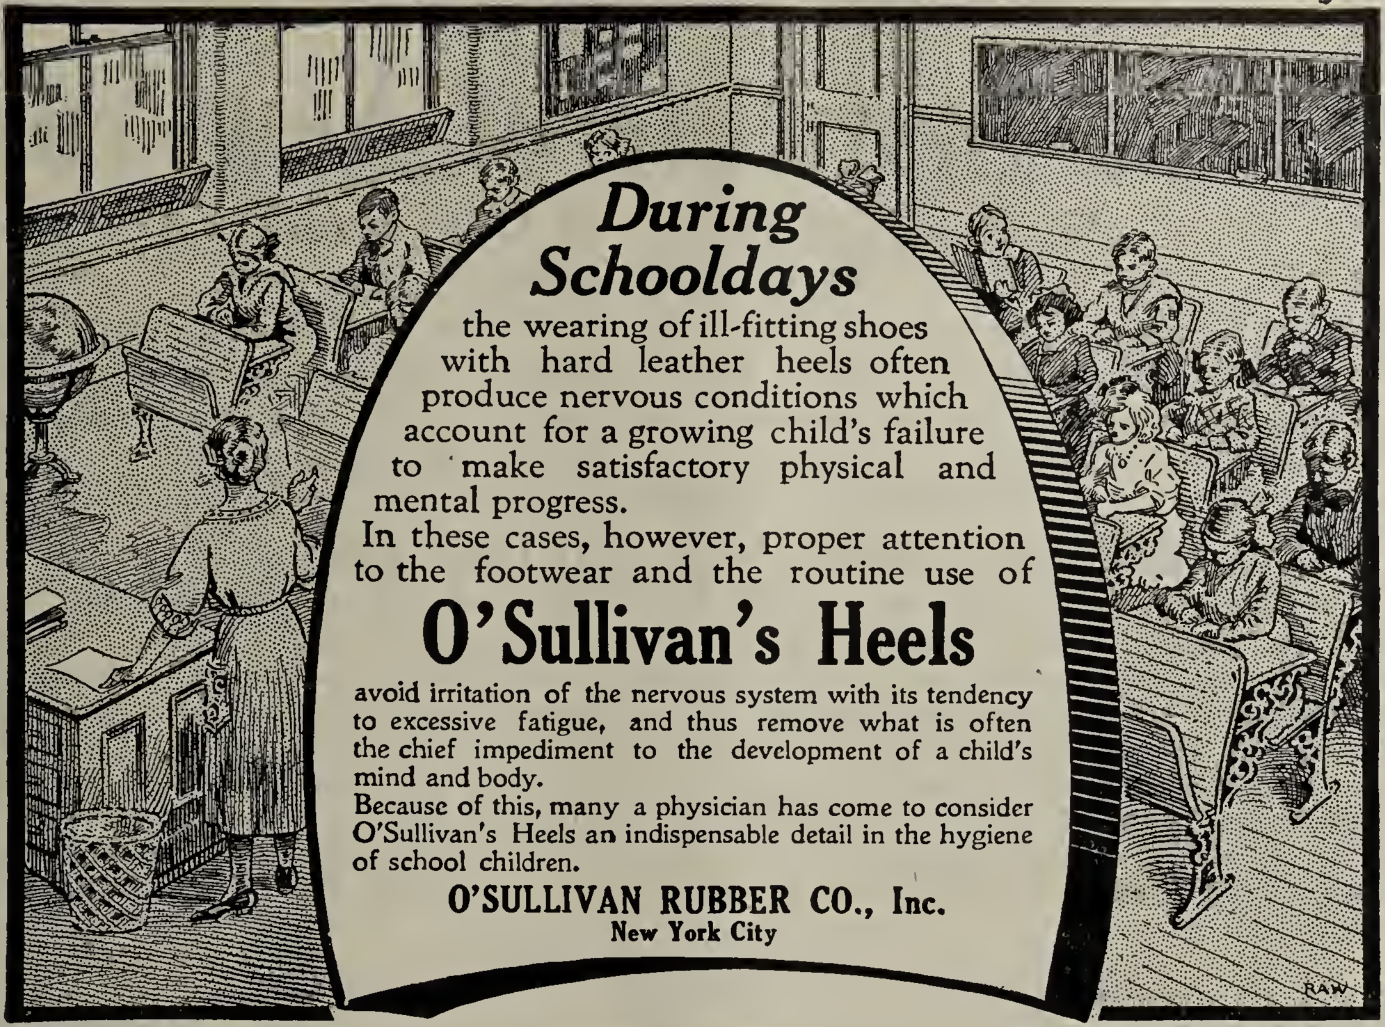
are best controlled by an effective combination of Rhubarb, Alkalies and Aromatics.

Alkarhein is an alkaline elixir, containing the active principles of rhubarb, berberine, soda bicarbonate, pancreatin, cinnamon and aromatics, and differs from ordinary Rhubarb Compounds in that its ingredients are first extracted with alcohol, and then only enough pure cane sugar added to prevent precipitation and render the product palatable. It does not cause fermentation.

Alkarhein is an excellent laxative, especially when hemorrhoids are present, soothes irritation, overcomes auto intoxication and inflammation, stimulates glandular secretion, opposes hypersecretion, hyperacidity and fermentation, and helps restore normalcy in the intestinal tract. It is pleasant in taste, prompt in action, satisfactory in effect.

ALKARHEIN can be used to advantage in your practice. Send for samples and literature.

FOUNDED 1828
THE WM S. MERRELL COMPANY
CINCINNATI. U. S. A.



During Schooldays

the wearing of ill-fitting shoes with hard leather heels often produce nervous conditions which account for a growing child's failure to make satisfactory physical and mental progress.

In these cases, however, proper attention to the footwear and the routine use of

O'Sullivan's Heels

avoid irritation of the nervous system with its tendency to excessive fatigue, and thus remove what is often the chief impediment to the development of a child's mind and body.

Because of this, many a physician has come to consider O'Sullivan's Heels an indispensable detail in the hygiene of school children.

ORGANIZED 1912

Radium Institute of New York

323 Riverside Drive—at 104th Street
Phone Academy 6100

An institution thoroughly equipped for the application and study of all types of radium therapeutics, and allied measures of treatment. Patients may be referred on orders from any physician or institution. Full medical and surgical hospital care.

PHYSIO-THERAPY DEPARTMENT

This important branch of the Institute is open for inspection of physicians and for the reception of patients. Electro-magnetic therapy of the most improved and modern type is administered under the direct supervision of a qualified staff. Cabinet electron emanators of deep penetration, adapted to the requirements indicated in the extreme chronic manifestations of Arthritis, Neuritis, Neurasthenia, Arterio-sclerosis, Cardio-vascular degenerations and the early senile period. Superior facilities offered the physician, enable him to check up the metabolism of his patient and co-operate in securing a more scientific application of physio-therapeutics. Particular attention is given to secure the complete comfort and privacy of each referred patient. Literature and special information on request. Consultation with the physician in charge is desired before patients are accepted.

C. EVERETT FIELD, M. D.
Director.

The Management of an Infant's Diet

Constipation

Protein indigestion or the failure to take care of the casein of cow's milk may result in delayed bowel movements.

When constipation in infancy is due to casein curds it is readily overcome by employing some means of preventing the firm coagulation of the casein.

Mellin's Food

acts upon the casein of milk in such a manner that the coagulated casein is presented in a most favorable condition for the action of the digestive fluids; therefore, Mellin's Food is especially indicated in constipation due to faulty protein digestion, and results will at once be apparent if Mellin's Food is used in sufficient amount to thoroughly attenuate the milk casein.

Mellin's Food Company, Boston, Mass.

LISTERINE

A Non-Poisonous, Unirritating, Antiseptic Solution

LISTERINE
LISTERINE
LAMBERT
LAMBERT
PHARMACAL COMPANY

Agreeable and satisfactory alike to the Physician, Surgeon, Nurse and Patient. Listerine has a wide field of usefulness and its unvarying quality assures like results under like conditions.

As a wash and dressing for wounds
As a deodorizing, antiseptic lotion
As a gargle
As a mouth-wash dentifrice

Operative or accidental wounds heal rapidly under a Listerine dressing, as its action does not interfere with the natural reparative processes.

The freedom of Listerine from possibility of poisonous effect is a distinct advantage, and especially so when the preparation is prescribed for employment in the home.

LAMBERT PHARMACAL COMPANY
SAINT LOUIS, MO., U. S. A.

CHRONIC CONSTIPATION

is most successfully treated by

a lubricating agent that will not upset the stomach, that effectually lubricates without impairing nutrition and will not cause seepage. The best agent to secure these results is the EMULSIFIED OIL in

ANGIER'S EMULSION

Its use eradicates the drug habit and the constant recourse to laxatives and aperients and furthermore ANGIER'S promotes nutrition.

Sig.: 1 or 2 tablespoonfuls in glass of hot water twice daily.

If you are not familiar with the Emulsion and you have a case where you would like to try some samples, we will send them charges prepaid on request

Treating

Open Wounds

with Radiant Light and Heat

The light induces hyperemia and therefore increases flow of blood. The dilated arteries prevent sloughing and promote more rapid repair.

A striking result of this treatment is healing *without scars.* No induration forms around the edges of the wound. For facial wounds this treatment is especially valuable.

Radiant Light and Heat, the wonderful remedial agents of Nature, are most effectively utilized by the

Thermolite

Radiant Light and Heat
Applicator

A scientifically designed appliance that reflects the light in *parallel* rays. There is no focal spot to burn or blister. *Safe as Sunlight.*

Thermolite is used in Government hospitals and in private practice in treating

Neuritis
Lumbago
Sprains
Colds

Rheumatism
Erysipelas
Eczema
Etc.

Genuine Thermolites have the name on the Reflector.

No. 0670 Office Applicator

Reflector 12" diam. Stand adjustable from 57" to 96" high. Consumes 375 watts at 120 volts A. C. or D. C. Covers 300 square inches 36" from reflector. Finish, Olive and Nickel. Price complete with stand, $30.00 each.

No. 0645 Hand Applicator

Same design as 0670 only 8" diam. Consumes 200 watts, 120 volts A. C. or D. C. Made of Aluminum, weight 16 oz. Finish, Black and Nickel. Price complete without stand, $10.00 each. Folding stand only for No. 0645, $6.00 each.

FOR REST AND RECREATION—

BERMUDA

THIS SUMMER

PHYSICIANS and their patients who need rest and quiet will find Bermuda the ideal place for a vacation.

The equable summer temperature averages 77° and there is an invigorating, cooling breeze 24 hours of every day. There are no noises—no railroads, trolleys, automobiles, or factories. Just the place to rest tired nerves.

For recreation there is the best surf and still-water bathing, sailing, canoeing, fishing, cycling, driving, tennis, golf on fine 18-hole courses, and sightseeing—including the Crystal Caves and Sea Gardens. Dances and parties at the hotels, too. In summer these 150 islands are a luxuriant panorama of exotic flowers in full bloom—oleanders, hibiscus, poinciana, bougainvillea, etc., all at their best.

Only two days from New York—a delightful summer sea voyage on palatial liners. No passports required.

Secure beautiful illustrated book from Furness Bermuda Line, 34 Whitehall Street, New York, or any travel agency, or

Weed Hay Fever

GIANT RAGWEED *Ambrosia trifida*

THE Late Summer and Early Autumn Type of Hay Fever is caused by many of the common weeds, as–Ragweed, Russian Thistle, Sage Brush –the species differing widely according to locality. To assure specific treatment diagnostic tests are essential. To assure preseasonal treatment early diagnoses should be made,–otherwise the less desirable, though often beneficial, coseasonal treatment will be involved. List of late flowering weeds, showing regional distribution and time of pollination, sent on request.

RUSSIAN THISTLE *Salsola pestifer*

SAGE BRUSH *Artemisia tridentata*

RADIUM EMANATION

AVAILABLE FOR THE FIRST TIME

RADIUM EMANATION is now available for the *first time* on short notice in any quantities or concentration desired.

RADIUM EMANATION is applicable to any therapy where radium salts are indicated.

RADIUM EMANATION may be put into containers of any desired shape, size and strength, permitting a flexibility impossible with radium salts.

RADIUM EMANATION implantation permits of a uniform distribution of greater intensity and makes possible the treatment of regions otherwise inaccessible.

Special instruments, screens and applicators furnished as desired.
Shipments over reasonable distances practical.
Telephone and telegraphic orders given prompt attention.

Our laboratories are under the direction of a highly skilled technical staff, qualified by long experience in the physics of Radium Emanation, insuring an accurate and comprehensive administration of our service.

The equipment used for the collection, purification, and measurement of Radium Emanation is the most modern and was especially designed by our consulting physicist, *William Duane, Ph.D., D.Sc.,* Prof. Bio-physics, Harvard.

We will gladly send Dr. Duane's brochure, *"The Use of Radium Emanation in the Treatment of Disease"* on request, with any additional information you may ask for.
